## Abstract

We study social learning using experiments where two people independently learn relevant information and can share their information to make accurate private decisions. Across three experiments, people are substantially less sensitive to information others discover than to equally-relevant information they discovered themselves. This holds when they must learn information from others through discussion; when the experimenter perfectly communicates the information; and even when participants observe others' information with their own eyes. Thus, our results stem not from a failure to elicit information from others but a systematic tendency to underweight it relative to one's own information. Our findings illustrate a powerful barrier to social learning that might underlie many documented cases of failure to learn from others.

**Keywords:** information aggregation, learning, social learning, experience effects

# 1 Introduction

We often learn new information through our own actions or experiences: experimenting with a new technology, trying out a new restaurant, or personally visiting several schools before choosing one. But the actions and experiences of *others* also present us with a vast trove of useful data. We can talk to others who have used the technology, read restaurant reviews, or ask other students or parents for their opinions. Efficient social learning requires us to elicit information from others and correctly aggregate it with our own private information. How well do people do this, and what frictions might prevent social learning?

We study these questions experimentally. In our first experiment, five hundred participants face a simple learning task: making incentivized guesses of the fraction of red balls in an urn. To inform their guesses, participants have access to two sets of draws with replacement from the urn. In a control condition, participants make both sets of draws themselves and then make a guess. In the main treatment condition, the information is instead split between two participants. Each gets one set of private draws and the chance to learn each others' draws in an unstructured face-to-face discussion. After the discussion, each participant makes a private guess about the contents of the urn. Participants face aligned incentives to share information since the earnings from one partner's randomly-selected guess are equally split between the two of them.

Absent frictions to social learning, participants should be equally sensitive to information they uncover themselves and information their partner uncovered.<sup>1</sup> Instead, we find that participants' guesses respond 54% less ( $p < 0.01$ ) to signals their partners uncover—and which they can access through the discussion—than to signals they uncover themselves. The low sensitivity to their partner's information is a mistake that reduces earnings: given the incentives for accurate guesses, an additional draw to one's partner improves one's earnings 82% less than receiving an additional draw oneself.

What drives this failure of social learning? First, it could reflect imperfect *communication*: participants might be reluctant to elicit or share information, or may mistrust others' competence or memory, preventing them from reliably learning what their

---

<sup>1</sup>We employ three empirical approaches to test this hypothesis—non-parametric, reduced-form, and structural—that impose different assumptions but yield similar results. We focus here on the reduced-form approach, which simply asks how much the average guess changes in response to an additional red (as opposed to white) draw—we call this the “sensitivity” to information or the “weight” placed on signals.

partner uncovered. Second, there might be a failure of *information aggregation*: participants might not appropriately combine others' information with their own when forming guesses. To test between these possibilities, we run a treatment in which communication frictions are shut down by design: the experimenter directly informs each participant about their partner's draws.

Removing communication frictions does not increase sensitivity to others' information, implying that our finding is driven by a systematic bias in information aggregation. When the experimenter perfectly communicates each partner's draws, participants' guesses are 87% less sensitive to others' information than to own signals ( $p < 0.01$ ). Discussion with one's partner after being informed of their draws by the experimenter still leads to 46% less sensitivity to the partner's information ( $p < 0.05$ ). People appear to treat others' signals as inherently less informative, even when communication is clear.

We replicate these findings and investigate additional mechanisms in a second experiment with 292 adults in the same setting.<sup>2</sup> Most strikingly, participants underweight their partner's information by 41% relative to their own signal even when they sit beside their partner and can observe them drawing balls from the urn *with their own eyes* ( $p = 0.04$ ). This result eliminates or diminishes any role for (i) distrust of the information communicated by the partner and/or experimenter, since the information is directly observed with one's own eyes; and (ii) the mode of presentation of the information, including both its visual salience and whether the information is learned draw-by-draw or communicated in summary form.

The third experiment demonstrates the external validity of our findings in a higher-literacy population. In a simpler between-subjects experiment with 4,489 participants from the UK and US on Prolific, we randomize the order of learning one's own signals versus a partner's signals. Again, participants are less sensitive to others' information than to their own, by 17% ( $p < 0.01$ ), despite it being perfectly communicated to them.<sup>3</sup> Presenting own and others' signals using visually identical animations does not reduce underweighting, nor does doubling the stakes of the experiment or reducing any sense of

---

<sup>2</sup>The intended sample size for this experiment was 800 participants. Data collection ended in March 2020 due to the Covid-19 pandemic. The pre-registered sample size was chosen to be powered to test for gender differences in treatment effects, as reported in Conlon et al. (2024). See more in Section 5.

<sup>3</sup>The magnitude of discounting of others' information is significantly lower in the online experiment than in the lab experiments. This difference could be because the online experiment generates less of a sense of playing with another person or of truly drawing the signals oneself. Indeed, participants are often less sensitive to treatments in online experiments (Gupta et al., 2021). Differences in the study populations between India and the US/UK may also matter.

competition by barring the partner from making any guess.

Participants appear largely unaware of their underweighting of others’ information, and this bias is not driven by differential up-front attention or later recall. In a debriefing survey at the end of the third experiment, 77% of participants reported that they treated their own and their partner’s information the same. Yet these same participants are 15% less sensitive to their partner’s information than to their own ( $p < 0.01$ ). In the survey, we also ask participants to recall their own and their partner’s draws from the last round of the experiment. Underweighting of others’ information is statistically significant ( $p = 0.06$ ) and quantitatively similar even among the majority of participants who perfectly recall their partner’s draws.

In our experiments and, arguably, in many natural environments, generating one’s own information requires taking action or experiencing something oneself, whereas learning from others is often more passive. We provide evidence that this difference can at least in part explain the bias against others’ information. Specifically, in our online experiment, we vary whether participants must click a button to generate their own draws or if they passively observe draws appearing on the screen with a label identifying each draw as ‘Your’ or ‘Partner’s’. When clicking to generate their “own” draws, they are 17 to 19% less sensitive to their partner’s information than to their own ( $p < 0.01$ ). In contrast, when they must take no action to generate their own information, this under-sensitivity falls to only 4%, significantly smaller than with active involvement ( $p < 0.05$ ) and not distinguishable from zero ( $p = 0.27$ ).<sup>4</sup> This finding suggests that in cases where people take active efforts to uncover others’ information, social learning might be more effective.

We view the main contribution of this paper as being to the literature on social learning that investigates how agents learn from others (see Mobius and Rosenblat 2014 for a review).<sup>5</sup> We provide evidence for a novel, potentially far-reaching bias in information aggregation that may hinder social learning whenever people have to aggregate their

---

<sup>4</sup>In a structural estimation, we do continue to find significant though reduced under-sensitivity even in this treatment.

<sup>5</sup>Existing research finds that people fail to fully account for the correlation structure of the information that reaches them (Eyster et al., 2018; Enke and Zimmermann, 2019) and instead naively average their social neighbors’ views or information (Chandrasekhar et al., 2020). In field settings, people sometimes also react very differently to information depending on the identity of the sender, e.g., they may react more to information coming from celebrities (Alatas et al., 2021) or from people who are socially or economically similar to them or who are of a particular gender (BenYishay and Mobarak, 2019; BenYishay et al., 2020).

own and others’ information. This phenomenon may underlie other documented cases of incomplete social learning, whether in agricultural technology adoption in the field (Foster and Rosenzweig, 1995) or observational learning in the lab (Weizsäcker, 2010). It could also play a role in explaining the often modest effects of interventions providing people with information regarding the experiences or outcomes of others (Haaland et al., 2022). It suggests that actively engaging people in the information discovery process might be a promising avenue for designing more effective interventions.

Our paper also relates to literatures on experience effects and reinforcement learning. Using observational data, previous work has shown that people’s beliefs and economic decisions are powerfully shaped by their personal experiences, even when much more complete data are easily available (Malmendier and Nagel, 2016; Malmendier et al., 2021; D’Acunto et al., 2021; Malmendier and Shen, 2024). Consistent with this, experiments on reinforcement learning show that people’s beliefs and actions react more to events that personally affect them (Merlo and Schotter 2003, Simonsohn et al. 2008, Miller and Maniadis 2012). Intuitively, the idea is that burning one’s hand on a hot surface is more impactful than watching someone else do it or being told about it. Our findings echo this idea, with an important difference: even *before* (or without) any consequences or feedback, people are biased against information from others. Our findings might thus apply to decisions where any payoff realization lies in the distant future, such as education or career choices.

More broadly, this paper adds to a growing literature on the drivers of under- and overreaction to information. Recent work mostly focuses on people failing to learn effectively on their own, including neglecting the strength of signals (Augenblick et al., 2024), being influenced by salient features (Bordalo et al., 2023), complexity and cognitive uncertainty (Enke and Graeber, 2023), selective attention (Ba et al., 2024; Schwartzstein, 2014), and the role of associative memory (Enke et al., 2024). We focus on inefficiencies in learning that may arise when some of the signals reach people from others. We also complement recent work showing ownership effects in learning, where people are more sensitive to information about goods they own compared to goods they do not own (Hartzmark et al., 2021). Our experiments suggest that similar notions of “ownership”—perhaps generated by taking actions to uncover the information—may extend to information itself.

Insufficient learning from others could arise in many real-world situations. For example, business analysts can learn information from co-workers or do the research them-

selves, educators can impart facts passively or invite students to discover them by trial and error, farmers can use new agricultural technologies themselves or learn from their neighbors about them (Kondylis et al., 2024), and medical experts may supplement their own judgment with information from AI tools (Agarwal et al., 2024). Our results suggest that people will be systematically less sensitive to information originating from others, even when that information is perfectly communicated.

An open question is how this bias plays out in the field and whether under-sensitivity to others’ information is a reasonable heuristic. In some situations, such as when returns to taking an action are idiosyncratic, information from others is truly less relevant to one’s own decisions. Alternatively, information received from others may be untrustworthy or correlated and thus one should react less to it relative to one’s own independent signals. However, in many cases, people have limited information from their own experiences while information from others is far more informative and reliable, so discounting others’ information is costly. More research is required to understand the prevalence and strength of the effect we document in natural settings.

The remainder of this paper is organized as follows. Section 2 presents the broad aspects of the design shared by the different experiments. Section 3 presents the empirical framework. Sections 4, 5, and 6 present the detailed designs and results of the three experiments. Section 7 discusses confounds and alternative interpretations. Section 8 discusses open questions and concludes.

## 2 Overview of Design

In all three experiments, participants play multiple rounds of the same basic statistical learning exercise: a balls-and-urns task based on a large literature studying individual learning (Benjamin, 2019). Here, we describe the task and features of our design common to all experiments. We defer the discussion of treatment variations and details specific to each experiment to the corresponding sections below.

The goal in the experimental task is to guess the number of red balls in an urn containing 20 balls. Participants are informed that the number of red balls in the urn is drawn uniformly from 4 to 16 in each round, as explained with the help of the illustration in Appendix Figure A.I(a) in the in-person experiments.<sup>6</sup> In the online experiment, we

---

<sup>6</sup>We avoided more extreme distributions—fewer than 4 or over 16 red balls out of 20—as these were

explain that “the computer will randomly choose the exact number of red marbles [in the urn], where every number between 4 and 16 was equally likely to be chosen.”

In each round, participants receive two independent, noisy signals about the composition of the urn, by privately drawing a number of balls from the urn with replacement.<sup>7</sup> The number of draws in each ‘signal’ is randomized—either 1, 5, or 9 draws—creating variation in how informed each participant is.<sup>8</sup>

Depending on the treatment condition, participants either play the game entirely on their own—the *Individual* treatment—drawing two sets of balls themselves, or else draw one set of balls themselves and have access to another set of balls that a partner (another participant in the experiment) drew. The different treatments vary how the information obtained by one’s partner can be learned: via open-ended discussion, directly communicated by the experimenter, and/or observed with one’s own eyes. Guesses are made after making each set of draws (or potentially learning them via their partner). We test for frictions in social learning by comparing the sensitivity of guesses to draws across conditions.

## 2.1 Incentives to Pool Information and Make Accurate Guesses

Participants have incentives both to make accurate guesses themselves and to help their partner do so by pooling information. The incentives provided were chosen to be easy for participants to understand: a penalty per ball away from the truth. Formally, each guess is incentivized by a piece-wise linear loss function.<sup>9</sup> In Experiments 1 and 2, a perfectly accurate guess earns each member of the pair Rs. 105 and the payment decreases by Rs. 15 per ball the guess deviates from the truth.<sup>10</sup> This incentive scheme was explained

---

more likely to generate signals with complete agreement between the two partners.

<sup>7</sup>In Experiments 1 and 2, participants physically drew balls from an urn in our lab, while in Experiment 3 (the online experiment), the drawing was simulated using an animation of an urn. In each case, participants were informed that both partners were drawing from the same urn. In Experiments 1 and 2, at least one participant was always present with the urn, eliminating any concern that the urn might be switched out between players.

<sup>8</sup>To be precise, we randomly choose the number of draws in the two sets of draws received in each round with uniform probability from  $\{(1, 1), (1, 5), (5, 1), (5, 5), (1, 9), (9, 1)\}$ . This excludes cases with more than 10 draws total.

<sup>9</sup>On top of their participation fee, each person receives a payment equal to  $\max\{(A - B \times |g - r|), 0\}$ , where  $g$  is the guess,  $r$  the true number of red balls for the randomly-selected guess, and  $A$  and  $B$  are constants.

<sup>10</sup>As we describe below, Experiment 2 also had a higher-stakes treatment in which incentives were increased by 50%.

to participants in Experiments 1 and 2 using the illustration shown in Appendix Figure A.I(b). These incentives are sizable. Rs. 105 is about \$1.50 and Rs. 15 is about \$0.20, while average daily earnings in our Chennai sample are about Rs. 350 (\$5).

Participants make multiple guesses throughout the experiment, and we randomly select one guess to score and pay participants for its accuracy. In Experiments 1 and 2, we select one guess among all the guesses that either partner made (including intermediate guesses). We then pay the two participants equally, irrespective of who made the guess, in separate envelopes at the end of the experiment. Thus, each person is incentivized to increase the accuracy of each guess from their pair. Neglecting to ask your partner for information, withholding information from them, or ignoring their information reduces their own expected payoff. In Experiment 3, the online experiment, participants never need to (and, indeed, cannot) communicate with each other, and information is shared by design. Each participant is rewarded for a randomly selected one of their own guesses, i.e., we do not split incentives between partners.

## 2.2 Complexity and Comprehension

We designed the experimental task to balance two goals. First, given the relatively low education and numeracy levels in the samples for Experiments 1 and 2, it was meant to be easy to understand and feasible for most participants. We therefore avoided eliciting probabilistic beliefs or employing difficult-to-explain scoring rules and used uniform priors as they are easy for participants to understand. We also provided training in the task to participants of Experiments 1 and 2 before the first round.<sup>11</sup> Participants individually played two unincentivized practice rounds with two guesses in each, and during these rounds received two ‘tips’ on making good guesses.<sup>12</sup> The vast majority understood the tasks, as measured by excellent performance on comprehension checks (Table A.I).

The simple setup of our experiment does not require participants to use others’ actions to make (potentially complex) inferences about their information. Nor must they

---

<sup>11</sup>Full experimental scripts are shown in Online Appendix C.

<sup>12</sup>The first tip explains that it makes sense to guess there are more red than white balls if you draw more red than white, and vice-versa. The second tip is that “the more balls you draw, the more confident you can be in your guess”. We note a possible caveat that some participants might have construed these tips to imply their ‘own’ information was more valuable than someone else’s. However, the tips were given in the context of a practice round where all balls were drawn oneself, so there was no implication of discounting others’ information. We did not provide these tips in Experiment 3 to mitigate any remaining concerns about this issue.

attempt to correct for any redundancy in the information that reaches them through multiple sources. Instead, participants in our experiment can directly learn their partner’s independent signal itself. This is in contrast to studies where participants observe other participants’ decisions, sometimes in complex real-world networks, and must both infer the underlying signals as best they can and then make decisions based on those inferences (Goeree et al., 2007; Reshidi, 2022; Chandrasekhar et al., 2020).

The second goal was to design a sufficiently complex task—as in many learning problems in the field—to create some ambiguity and wiggle room for biases and heuristics to enter participants’ decision-making. Making the optimal guess sufficiently easy to compute—e.g., with very few states or possible signals—might have potentially eliminated all biases since the correct action would become obvious to everyone.

A caveat resulting from the above design choices is that we do not, strictly speaking, measure participants’ beliefs about the color composition of the urn. Doing so would involve eliciting their full probabilistic belief distribution, or at least attempting to elicit the mean (or median or mode) of their belief distribution by employing a proper scoring rule (Palfrey and Wang, 2009). The incentives we employ do *not* constitute a proper scoring rule, and the optimal guess of a participant is not generally their mean or modal belief.<sup>13</sup> Guesses should therefore be thought of as actions that participants have an incentive to tailor to the signals they receive. Our empirical tests examine whether these guesses are equally sensitive to one’s own and others’ signals. However, as a benchmark, we also compute what a risk-neutral Bayesian seeking to maximize expected payoffs would guess given the signals and our incentive structure. In addition, our structural model accounts for the incentive structure faced by participants.

---

<sup>13</sup>Practically speaking, our goal was for participants to understand that they face an incentive to pay attention to information, think about it, and try to make accurate guesses. We avoided using more complex scoring rules such as quadratic or binarized scoring due to the difficulty of explaining them even to higher-education populations (Danz et al., 2022). A simpler alternative would be to pay a reward if a participant guessed the truth exactly while paying zero otherwise. This has the attractive feature of giving the participant incentives to report the mode of their belief while still being easy to understand. We did not pursue this route since we felt it might be perceived as unfair by participants and could cause disappointment or ill will, making subsequent recruitment harder. That said, our incentive scheme is close to a proper scoring rule for the median of the Bayesian posterior under risk neutrality, due to its absolute value form. The exception is following rare extreme draws (mostly red or mostly white) where the truncation of the loss function at zero incentivizes shading the guess towards 50% red.

### 3 Empirical Framework

Our goal is to test whether individuals’ guesses are equally sensitive to signals drawn by themselves versus by others. We further examine how this depends upon the precise mode of social learning, such as whether the partner’s information must be learned through a discussion, is communicated by a third party (the experimenter), and/or is directly observed. We present three types of empirical analyses—non-parametric, reduced form, and structural—to answer these questions. These three approaches impose different assumptions and have different strengths, but ultimately lead to similar conclusions.

#### 3.1 Non-parametric Approach

In the non-parametric approach, we use minimal assumptions and simply plot average guesses in each treatment against the signals drawn. For simplicity, we summarize each signal by the net number of red draws (i.e., the number of red minus the number of white draws). That is, if a participant saw 4 red draws and 1 white draw, we would classify the signal as being 3 net red draws.<sup>14</sup> To enable a transparent comparison of the sensitivity of guesses to own versus others’ signals, we plot the guesses separately against the signals drawn by oneself versus those drawn by one’s partner.

#### 3.2 Reduced-form Approach

In our second empirical approach, we impose a linear relationship between signals and the resulting guesses and test for differences in this relationship across treatments. The starting point for our analysis is estimation of the following equation by OLS, separately by treatment:

$$Guess_i = \alpha + \beta^o \cdot Own\ Info_i + \beta^p \cdot Partner's\ Info_i + \epsilon_i \tag{1}$$

where  $Guess_i$  is  $i$ ’s guess of the number of red balls (after having a chance to learn both signals), and  $Own\ Info_i$  and  $Partner's\ Info_i$  are the net number of red draws (i.e., red

---

<sup>14</sup>This simplification loses some information, e.g., it does not capture the total number of draws. A signal with 1 net red could come from a single draw of a red ball or from 9 draws with 5 red and 4 blue. A Bayesian should react differently to these two signals. The structural model does not share this weakness.

minus white draws) drawn oneself and by one’s partner respectively.  $\beta^o$  and  $\beta^p$  capture the sensitivity of participants’ guesses to signals drawn themselves and by others. If participants learn their partner’s signals and treat them the same as their own signals, it should be that  $\beta^o = \beta^p$ . If instead  $\beta^p < \beta^o$ , participants in that treatment are less sensitive to their partner’s draws than to their own.

When estimating equation (1), we add controls for the order in which participants complete the different treatments. In all three experiments, participants play multiple rounds of the game, doing the different treatments in randomized order. Although they receive no feedback after each round, and thus the scope for learning is limited, we control for treatment order effects by including dummies for round number interacted with *Own Info<sub>i</sub>* and *Partner’s Info<sub>i</sub>*.<sup>15</sup>

We also control for the possibility that differences between  $\beta^o$  and  $\beta^p$  may reflect ‘information order’ effects: i.e., the order in which one receives information may affect the weight placed on it. For a Bayesian, the order of receiving information should not matter. Nonetheless, ex ante it is possible that participants put more weight on signals they saw first (‘first impressions matter’) or on signals they saw last (‘recency effects’). In Experiment 3, the order of learning one’s own and one’s partner’s signals is randomized with equal probabilities, so the comparison between  $\beta^o$  and  $\beta^p$  is unbiased by information order effects. In Experiment 1, instead, participants learn their partner’s signals only after they have received their own signals. Therefore, we compare  $\beta^p$  in these treatments with the coefficient on one’s own *second* set of draws in the *Individual* treatment, estimated as  $\beta_2^o$  in the following regression:

$$Guess_i = \alpha + \beta_1^o \cdot Own\ First\ Info_i + \beta_2^o \cdot Own\ Second\ Info_i + \epsilon_i \quad (2)$$

In practice, we find that participants tend to put more weight on the signals they receive *second*, so treatments that provide partners’ information last would tend to bias us *against* finding under-sensitivity to others’ information.<sup>16</sup>

---

<sup>15</sup>To include these controls, we stack the regressions for all treatment conditions in a given experiment and estimate them jointly in one regression, allowing the coefficients  $\alpha$ ,  $\beta^o$  and  $\beta^p$  to vary by treatment.

<sup>16</sup>Experiment 2 has aspects of the design of both Experiment 1 and Experiment 3. Some comparisons involve a randomized order of receiving information, as in Experiment 3. Others are similar to Experiment 1 in that one’s partner’s information is received after one’s own information.

### 3.3 Structural Approach

In our third empirical approach, we estimate a simple model of quasi-Bayesian updating. This approach has several strengths relative to the reduced-form analysis. First, it exploits the full information content of the signals, including the number of draws, rather than the simplified ‘net red draws’ employed in the reduced form. Second, it accounts for the incentive structure faced by participants, modeling them as risk-neutral agents trying to maximize expected payoffs given their beliefs. Third, by taking the form of a standard learning model, it allows us to estimate interpretable weights placed on one’s own and others’ signals, with a clear Bayesian benchmark. Finally, it also accounts for noisy choice together with censoring in guesses at 4 and 16, which might otherwise cause guesses to appear less sensitive than those of a risk-neutral Bayesian. On the other hand, the structural model makes more assumptions than the non-parametric and reduced-form analysis, including imposing risk-neutrality.

Let  $d_1$  be the participant’s own signal and let  $d_2$  be her partner’s signal, e.g.,  $d_1$  might equal {Red, Red, White, Red, White} and  $d_2$  might equal {Red}. We then assume that the participant updates her beliefs about the state of the world  $s$  (the number of red balls in the urn) according to a modified version of Bayes’ Rule:

$$Posterior(s|d_1, d_2) \propto Prior(s) * P(d_1|s)^{\omega_{1rt}} * P(d_2|s)^{\omega_{2rt}} \quad (3)$$

where  $Prior(s)$  is the participant’s prior about the probability of state  $s$ , and  $P(d_i|s)$  is the (objective) probability of observing a set of draws  $d_i$  conditional on state  $s$ . Recall that participants are told each state is equally likely, and there are 13 possible states  $s \in \{4, 5, \dots, 16\}$ , so  $Prior(s) = \frac{1}{13}$ . Next,  $\omega_{1rt}$  and  $\omega_{2rt}$  are the weights that the participant puts, respectively, on her own and her partner’s signals in treatment  $t$  when that round occurs in chronological order  $r$ . For  $\omega_{1rt} = \omega_{2rt} = 1$ , Equation (3) reduces to Bayes’ Rule.

We allow  $\omega_{1rt}$  and  $\omega_{2rt}$  to differ from the Bayesian benchmark depending on both the treatment condition and the chronological order of the round. In particular, we assume the following functional form to mirror the reduced-form analysis described above:

$$\begin{aligned} \omega_{1rt} &= \beta_{1t} + \mu_{1r} \\ \omega_{2rt} &= \beta_{2t} + \mu_{2r} \end{aligned}$$

where  $\beta_{1t}$  and  $\beta_{2t}^p$  are, respectively, the weight the participant puts on her own and her partner’s signal (or, in Experiment 1’s *Individual* treatment, on her own second signal) in treatment  $t$ , and  $\mu_{1r}$  and  $\mu_{2r}$  are the additional weight she puts on each signal when that treatment occurs in chronological order  $r$ .

Just as with the reduced-form analysis, we control for the order in which information arrives in one of two ways. In Experiment 1, the partner’s information is always conveyed second, so we use a control condition (the *Individual* treatment) where both signals are drawn by the participant herself. We then compare  $\omega_{2rt}$ , the weight on the second set of draws across treatments to identify the effect of drawing information oneself net of any information order effects. In Experiment 3, we randomize whether participants’ own information or their partner’s information comes first, so  $\omega_{1rt}$  and  $\omega_{2rt}$  will not be biased by differential treatment of earlier or later signals.

In addition to systematically biased updating, we allow for noisy choice. Doing so allows us to account for heterogeneity in guesses conditional on signals (i.e., not everyone with the same signals makes the same guess). We assume that agents are risk-neutral but calculate the expected payoff of each possible guess with noise. In particular, let  $Earnings(g, s)$  be the earnings that a participant would earn if they made guess  $g$  and the true state was  $s$ . Given the experimental incentives,  $Earnings(g, s) = \max\{0, 105 - 15 * |g - s|\}$ . We assume that the agent calculates the expected payoff of each guess  $g$  using the (potentially biased) updating rule given by Equation 3 plus a random additive error term. That is, we assume the perceived expected payoff from making guess  $g$  given draws  $d_1$  and  $d_2$  is given by

$$EP(g|d_1, d_2) = \sum_{s=4}^{16} Posterior(s|d_1, d_2)Earnings(g, s) + \alpha\epsilon_{i,g}. \quad (4)$$

The agent then chooses the guess that maximizes this perceived expected payoff. For simplicity, we assume  $\epsilon_{i,g}$  is i.i.d. Type 1 extreme value. The parameter  $\alpha$  then governs the extent of noisy choice.<sup>17</sup> We estimate the model by maximum likelihood.<sup>18</sup>

---

<sup>17</sup>See Goeree et al. (2007) for an example of a similar model of noisy discrete choice in a balls-and-urns decision problem.

<sup>18</sup>In particular, given the assumptions above, the probability that an agent with signals  $d_1$  and  $d_2$  will choose guess  $g$  is  $P(i \text{ guesses } g|d_1, d_2) \propto \exp\left(\frac{1}{\alpha} \left[ \sum_{s=4}^{16} Posterior(s|d_1, d_2)Earnings(g, s) \right]\right)$ . We then choose parameters that maximize the joint likelihood of observing all the choices in our data. We calculate standard errors by bootstrapping the data, drawing pairs with replacement from the

## 4 Experiment 1: Establishing the Main Results

### 4.1 Recruitment and Sample

Experiment 1 was conducted in person at the Behavioral Development Lab in Chennai, India, between July and December 2019. Participants were recruited on a rolling basis, with about 4 to 10 individuals completing the experiment on a given day. We recruited individuals—not pairs—residing in low- to middle-income neighborhoods within a reasonable travel time of the lab. Surveyors went door-to-door to advertise an academic study on ‘your choices and how you aggregate information’ which would ‘help us understand how you make decisions’. No more specific study details were provided at this stage. Potential participants were informed that they would spend 2 to 3 hours at the study office and could expect to earn Rs. 150 to 280 (\$2 to \$3.90) per person, plus a payment of Rs. 100 (\$1.40) to cover travel expenses. Recruitment stopped when we reached our pre-specified target of 500 individuals. Participants were randomly assigned to pairs within an experimental session.<sup>19</sup>

Column 1 of Table 1 reports demographic characteristics of our sample. 50% of the participants are male. Participants are on average 35 years old and have a bit less than 8 years of education. Participants answered about 80 percent of comprehension questions correctly on the first attempt, indicating fairly high levels of attention and comprehension for a task that was unusual and somewhat complex given the local context.

### 4.2 Experiment 1: Design

Participants play five rounds of the task, as illustrated in Figure 1, with no feedback between rounds.<sup>20</sup> Participants first play, in randomized order, an *Individual* round and a *Discussion* round. In each round, participants have access to two sets of draws with

---

data. Throughout, we report bootstrapped standard errors for legibility but denote significance using bootstrapped confidence intervals (e.g., an estimate is significant at the 5% level if the center 95% of bootstrapped estimates do not include zero).

<sup>19</sup>Each participant plays four of their five rounds with one randomly-assigned partner of a different gender, and one round with a randomly-assigned partner of the same gender. Participants were introduced to their partner at the start of each round. This variation was induced to study the effect of gender composition on learning and to contrast these findings with a study of learning between spouses. These results are reported in a companion paper. Here, we pool results across gender and both types of pairs.

<sup>20</sup>The full experimental script is provided in Appendix C.1.

1, 5, or 9 draws each.

***Individual round.*** In the *Individual* round, the participant first draws a set of balls from the urn with replacement, followed by a guess of how many red balls are in the urn. Then, they draw a second set of balls from the urn and make a second (and final) guess. All drawing and guessing are done privately, without any need to share information. This round serves as a control condition—a benchmark against which we compare the other treatments.

***Discussion round.*** The *Discussion* round models a common mode of social learning, where we learn from others’ experiences through direct communication with them. Instead of drawing two sets of draws oneself as in the *Individual* round, each participant’s *partner’s* draws—accessible through a discussion—serve as their second set of draws. Each person first makes one set of draws followed by a private guess, exactly as in the *Individual* round. Next, the pair are asked to hold a face-to-face discussion and enter a joint guess.<sup>21</sup> After their discussion, the teammates are separated and each person makes one final, private guess.

Participants can take as long as they like for the unstructured, face-to-face discussion with their partner. They have an incentive to share information since one guess per team is randomly chosen to be paid for accuracy at the end of the experiment, with the payment split between the two partners. Participants also have an incentive to help their partner deliberate and make better guesses conditional on information, as in Cooper and Kagel (2005). We record the audio of the discussion (with participants’ consent) and later analyze the transcripts, as reported in Table A.II.

Comparing each participant’s final guesses in the *Individual* and *Discussion* rounds reveals whether they learn as much through a discussion with a partner as from information they uncovered themselves. By design, participants have access to the exact same number of draws to inform their final guess in these two rounds, provided they share information.<sup>22</sup> If participants are instead less sensitive to information collected

---

<sup>21</sup>The joint guess was included as a comparison to joint guesses made by teams composed of married couples and is not the focus of this paper. Note that having to enter a joint guess might cause teammates to come closer to agreement about the optimal guess, which might be expected to reduce under-sensitivity to each others’ information. Experiment 3 and most treatments in Experiment 2 do not include such a joint guess.

<sup>22</sup>To allow a particularly sharp comparison between the *Individual* and *Discussion* rounds, we ensure that exactly the same number of draws is available to each individual by the end of each round. For instance, suppose that an individual (call them Person 1) gets  $n_1$  draws first and  $n_2$  draws second in the *Individual* round, for a total of  $n_1 + n_2$  draws. We ensure that their partner (‘Person 2’) in turn

by their partner, this implies either a failure of communication or a failure to aggregate information provided by one’s partner.

Participants next play three more rounds, in randomized order, consisting of a second *Discussion* round and two additional treatments in which the experimenter informs the participant of their partner’s draws or guesses.

***Informed of Partner’s Draws* round.** This round (which we abbreviate as the ‘*Informed*’ round) is designed to shut down any communication frictions between the partners. It is identical to the *Discussion* round except that after participants receive their first set of draws and enter their first guess, they are told their partner’s draws (both number and composition) directly by the experimenter, e.g., “Your partner had five draws, of which three were red and two were white.” Participants then make an additional private guess, which can incorporate both sets of draws, before moving on to the discussion and their final private guess.

Comparing the guess made after the experimenter informs the participant of their partner’s signal (but *before* discussion) with the second guess in the *Individual* round allows us to directly test whether participants use information they gathered themselves in the same way as information collected by others but perfectly shared with them by a third party. In each case, there is no possibility of joint deliberation.<sup>23</sup> Finally, the *post*-discussion guesses in the *Informed* round reveal how participants use information shared by a third party when additionally given the chance to confirm the information with its source (their partner) and deliberate.

***Informed of Partner’s Guess* round.** This round is the same as the *Informed of Partner’s Draws* round except that the experimenter informs each person of their partner’s private guess (made based on their own draws only), rather than their partner’s draws. The experimenter also shares the number of draws this guess was based on, e.g., “Your partner had 5 draws and, after seeing these draws, they guessed that the urn contains 12 red balls.” Thus, while in the *Informed of Partner’s Draws* round we directly transmit the signal received by one’s partner, in the *Informed of Partner’s Guess* round we transmit the action (guess) taken based on that signal as well as a

---

receives  $n_2$  and then  $n_1$  draws in the *Individual* round. Then, to make the *Discussion* round comparable, we assign Person 1 to receive  $n_1$  draws and Person 2  $n_2$  draws in this round, such that if they pool information each will again have access to  $n_1 + n_2$  draws.  $(n_1, n_2)$  are randomized across pairs. In the other rounds,  $(n_1, n_2)$  are randomized independently within-pair across rounds.

<sup>23</sup>Note that this comparison requires controlling for round order effects, since the *Individual* round is always in the first two rounds, while the *Informed* round falls in rounds 3-5.

measure of the precision of the signal. This round parallels more closely the literature that investigates social learning based on observing others’ actions (Weizsäcker, 2010). In this treatment, less information is transmitted to the participant. Moreover, beliefs about others’ competence might affect how these actions are interpreted and how much is learned about the signals.

## 4.3 Experiment 1: Results

### 4.3.1 Non-parametric results

Before comparing participants’ guesses across treatment conditions, we show evidence of good comprehension of the task. Figure 2 Panel A examines participants’ first guesses, made after drawing the first set of balls by themselves. Reassuringly, the average number of red balls guessed increases in the number of “net red” draws uncovered oneself (pooling across all treatments), implying that participants respond to information they receive. We can compare this sensitivity to a normative benchmark by computing, for each guess that participants make, what a risk-neutral Bayesian seeking to maximize expected payoffs would guess given the same signals and faced with our incentive structure. On average, participants’ individual guesses (blue dots and lines) are fairly close to this benchmark (pink dashed lines), though somewhat less sensitive to signals than a risk-neutral Bayesian would be. Pooling across all data, the average participant guess increases by 0.61 percentage point for every 1 percentage point increase in what the risk-neutral Bayesian would guess.<sup>24</sup>

Figure 3 contrasts the sensitivity of participants’ guesses to their second set of draws in the *Discussion* and *Informed* rounds, comparing each to the *Individual* round. The blue curve representing the *Discussion* round (Panel A) is distinctly flatter than the grey curve representing the *Individual* round, revealing that participants’ guesses are less sensitive to information gathered by their partner compared to information they collected themselves. This difference is statistically significant: we can reject ( $F$ -test,  $p = 0.001$ ) that the differences in average guesses across treatments for each ‘net red’

---

<sup>24</sup>The lower sensitivity compared to the risk-neutral Bayesian could be due to conservatism in updating (consistent with the large literature on updating tasks similar to ours, see Benjamin 2019), to risk aversion, or to noisy guessing combined with censoring. We do not seek to disentangle these explanations, as our focus is instead on testing whether guesses respond differently to information depending on the source by contrasting behavior *across* treatments. The structural estimation accounts for noisy guessing and censoring in the data.

value are all zero (i.e., that for each pair of dots in Figure 3 the true values lie on top of each other).

Strikingly, the curve is even flatter in the *Informed* round (Panel B), in which we plot participants' guesses after their partners' information is *directly* communicated to them by the experimenter (and before any joint deliberation with their partner). Despite having been given *all* decision-relevant information about their partner's draws directly, participants react to this information much less than they do to information they collected themselves. We can again reject that average guesses conditional on each 'net red' value are always equal across treatments ( $F$ -test,  $p < 0.001$ ).<sup>25</sup> This result suggests that the key friction is not communication (i.e., participants never learning the information from their partner) but instead, participants underweighting information uncovered by their partner, even when it is communicated. By design, this behavior cannot be explained by failure to communicate information or by mistrust of the partner's memory, ability, or motives.<sup>26</sup>

Panel C of Figure 3 shows a similar, though somewhat less pronounced, under-sensitivity to partner's information in *Informed* round's post-discussion guesses compared to the pre-discussion guesses shown in Panel B. Since participants can confirm the information given to them by the experimenter directly with its source (their partner), this suggests that low sensitivity to others' information is not primarily driven by mistrust in the experimenter (though we cannot rule out some role of mistrust in the pre-discussion guesses of the *Informed* rounds).

### 4.3.2 Reduced-form and structural results

The reduced-form and structural models provide quantitative estimates of sensitivity to own and others' information. Figure 4 plots participants' average sensitivity to the second set of signals, by treatment, using reduced-form estimates from Equation (1).<sup>27</sup> In their final private guesses in the *Discussion* round, participants are less than half as

---

<sup>25</sup>This graph depicts the second private guess—after being informed of one's partner's draws but before having a chance to discuss with them. This provides a clean comparison with the individual round: the only difference is drawing the signals oneself versus being informed of the signals one's partner drew.

<sup>26</sup>Recall that we always shuffle the balls in between draws. Thus, there is no (rational) notion of "ability" in terms of drawing balls.

<sup>27</sup>Recall that these estimates hold the order of receiving the information fixed: we compare sensitivity to the second set of draws across treatments.

sensitive to their partner’s signals (second bar) compared to the corresponding signals in the *Individual* round (first bar,  $p < 0.01$ ).<sup>28</sup> This implies they respond less to information their partner collected than to their ‘own’ information. Even more starkly, participants put close to zero weight on their partner’s information in the *Informed* round, right after it is *directly* shared with them (third bar,  $p < 0.01$ ). Adding a face-to-face discussion with their partner after being informed of their draws somewhat increases participants’ sensitivity to their partner’s signals. Still, it remains significantly below the sensitivity to their own signals (fourth bar,  $p = 0.02$ ).

The corresponding regression estimates are presented in Table 2 Panel A (columns 1 to 4). Comparing the coefficient  $\beta_2$  on the second set of information by treatment condition shows a clear result. Participants are 54 percent (0.28/0.52) less sensitive to information collected by their partner in the *Discussion* round relative to information they collected themselves in the *Individual* round ( $p < 0.01$ ). Even more strikingly, they are 86 percent (0.45/0.52) less sensitive to their partner’s draws in the pre-discussion *Informed* guess compared to in the *Individual* round ( $p < 0.01$ ). Put differently, participants are seven times more sensitive to their own information than to their partner’s, and we cannot reject that participants put no weight on their partner’s information at all. The face-to-face discussion increases sensitivity to the partner’s information relative to the pre-discussion guess, perhaps through joint deliberation regarding the right answer or increased trust in the information about the partner’s signal.<sup>29</sup>

The structural estimates in Table 2 Panel B mirror the reduced-form results. Column 1 shows that participants put close to the Bayesian weight ( $\beta_1 = 0.92$  vs. the Bayesian benchmark of 1) on their own first signal in the *Individual* treatment, and somewhat greater weight ( $\beta_2 = 1.50$ ) on their second signal in that round. In contrast, participants put much less weight on their partner’s information in the *Discussion* and *Informed* rounds. Most strikingly, participants put no weight at all on their partner’s signals in the (pre-discussion) *Informed* round. The weight on others’ information is somewhat

---

<sup>28</sup>For a risk-neutral Bayesian, this sensitivity would be around 0.72: that is, for every additional net red draw, the expected-payoff maximizing guess on average increases by 0.72. Participants’ sensitivity to signals in the *Individual* round is 0.52, so discounting of partners’ signals moves participants further away from the risk-neutral rational benchmark.

<sup>29</sup>The pattern of results in the *Informed of Partner’s Guess* round are similar or more extreme than those that we find in the *Discussion* and *Informed of Partner’s Draws* rounds. In the reduced-form estimates, participants are 85% less sensitive to their partner’s information in this treatment. Because lower sensitivity to others’ information in this treatment can be explained by additional factors such as guesses containing less information than draws or players’ beliefs about their partners’ ability to make good guesses, we defer the analysis of the *Informed of Partner’s Guess* round to Appendix B.1.

higher in the rounds involving discussion but still 69% to 74% lower than in the *Individual* round.<sup>30</sup>

**Earnings implications.** The expected earnings from guesses are a direct measure of performance in the experiment. Table 3 estimates average expected earnings from guesses as a function of the number of draws in each set of signals. As expected, more draws in the second set of signals in the *Individual* round significantly increases earnings, by Rs. 3.31 per extra draw. However, participants earn only Rs. 0.57, 82% less ( $p = 0.03$ ), for each extra draw their partner makes in the *Discussion* round and Rs. 0.50, 85% less ( $p = 0.01$ ), for each draw their partner makes in the pre-discussion guess in the *Informed* round. In the post-discussion guess in the *Informed* round, additional draws by the partner also earn less than own draws in the *Individual* round (Rs. 2.10 vs Rs 3.31), though this difference is not statistically significant ( $p = 0.32$ ).<sup>31</sup>

## 5 Experiment 2: Exploring Mechanisms and Confounds

Why do participants discount their partner’s information even when it is directly communicated to them? Experiment 2 is designed to isolate potential mechanisms, rule out potential confounds, and evaluate the robustness of our findings.

### 5.1 Recruitment and Sample

Experiment 2 was run at the Behavioral Development Lab in Chennai, India between February and March 2020, after observing the results of Experiment 1. We recruited new participants following a similar procedure as Experiment 1. Data collection ended in March 2020 due to the Covid-19 pandemic, with a sample size of 292 participants (out

---

<sup>30</sup>The parameters of the quasi-Bayesian model have a different scale and interpretation than the reduced-form results discussed above. But frictionless social learning implies  $\beta_2^o = \beta_2^p$  in both cases, where  $o$  and  $p$  refer to own and partner’s draws respectively. Appendix B.2 shows that the reduced-form and structural estimates are consistent with each other: data simulated using the structural model produces the same reduced-form results as the empirical data.

<sup>31</sup>Appendix Table A.III shows similar regressions but where the dependent variable is the absolute difference between participants’ guesses and the true number of red balls in the urn. Mirroring the results in Table 3, additional draws by the participant reduce this error on average, but this improvement is 75% smaller for draws that come from participants’ partners in the *Discussion* round. For the two guesses in the *Informed* round, we cannot reject that additional draws do not reduce the guessing error at all.

of an intended sample of 800).<sup>32</sup> Compared to Experiment 1, participants have a similar average age (38 versus 35) and years of education (9 versus 8), but are less likely to be female (31% versus 50%), as reported in column 2 of Table 1.

## 5.2 Experiment 2: Design

Participants played six rounds corresponding to different treatment conditions, with no feedback between rounds. They first played a *Discussion* round, exactly as in our first experiment, to replicate our earlier findings and provide a baseline to compare other treatments with.<sup>33</sup> They then played five rounds in randomized order, consisting of an *Informed* round just as in Experiment 1 and four additional variations of the *Informed* round, described below.<sup>34</sup>

**Observe Partner’s Draws round.** In this round (which we abbreviate to ‘*Observe*’), both participants are in the same booth, so they can each watch their partner drawing balls from the urn with their own eyes.<sup>35</sup> After both participants have drawn their signals they are separated and each makes a private guess. There is no discussion between partners and no need for the experimenter to share draws. Nor is there any scope for distrust of the experimenter or partner. Both one’s own and one’s partner’s signals are perfectly observable and revealed draw-by-draw in randomized order across individuals. The *only* difference between the two sets of draws is who physically drew the balls from the urn. We designed this to be an extreme treatment, where we anticipated equal sensitivity to one’s own and others’ information. The remaining treatments are subtler and largely subsumed under this treatment.

**Draw-by-Draw round.** In the *Informed* treatment, there are several differences in how participants learn about their own and their partner’s information. One such difference is that they draw their own signals one at a time from the urn, while their

---

<sup>32</sup>The pre-registered sample size was chosen to be powered to test for gender differences in treatment effects (which we explore in other work). Thus, even though the final sample size is smaller than intended, we remain tolerably well-powered to estimate the treatment effects described here. For example, the minimum detectable effect size for the *Informed* treatment is around 50% lower sensitivity to partner’s information relative to own information. This is close to the estimated effect in Experiment 1.

<sup>33</sup>Participants always played the *Discussion* round first in order to avoid the possibility that our new treatments primed participants to behave differently in the *Discussion* round, and thus provide a cleaner test of whether the *Discussion* results replicated.

<sup>34</sup>Appendix Figure A.II, Panel A, illustrates the design of the new treatment conditions in this experiment. The full experimental script is provided in Appendix C.2.

<sup>35</sup>We would like to thank Christine Exley for suggesting this treatment.

partner’s information is communicated in summary form in a single report (‘2 red and 3 white balls’). Certain updating biases (e.g., base-rate neglect) could cause participants to respond differently to summary information than to learning information draw-by-draw. To test for this channel, the *Draw-by-Draw* round proceeds identically to the *Informed* round, except that the experimenter shares their partner’s draws with each participant one draw at a time, e.g., by saying, ‘Your partner first drew a red ball’, then after a brief pause, ‘Your partner then drew a white ball, ...’ and so on.

***Reverse-Order* round.** In this round, one participant learns their partner’s signal before making any draws themselves. They then make a guess, make their own draws, and make another private guess. Since this treatment is only possible for one person in each pair, we only include guesses from the treated person while analyzing this round.

***No-First-Guess* round.** This round was identical to the *Informed* round except that participants do not make a guess directly after making their own set of draws. We implemented this change to test whether, for example, people are more open to others’ information when they have not yet taken an action or stated a belief based on their own information.

***Higher-Stakes* treatment.** We increased the incentives for accurate guessing by 50% in a randomly-chosen 3 out of 6 rounds. The maximum amount each individual could earn from a guess and their loss in earnings per ball away from the truth were both increased by 50%, to Rs. 158 (\$2.25) and Rs. 22.5, respectively. Participants were informed about the stakes at the beginning of each round.

### 5.3 Experiment 2: Results

Figure 5 shows the results from Experiment 2. Since this experiment does not include an *Individual* round, we simply compare the sensitivity to own information ( $\beta^o$ ) and the partner’s information ( $\beta^p$ ) within round, estimating Equation (1) by OLS.<sup>36</sup> The corresponding regression coefficients are presented in Panel A of Table 4.<sup>37</sup>

---

<sup>36</sup>We did not include an *Individual* round since the previous experiment established that, if anything, participants are more sensitive to their most recent signals compared to earlier signals. Thus, if the partner’s information is learned last, this biases us *against* finding less sensitivity to others’ information.

<sup>37</sup>Appendix Figure A.III, Panel A shows non-parametric estimates, plotting participants’ guesses first against their own signal and then against their partner’s signal in the *Discussion*, *Informed*, and *Observe* treatments. Like the reduced-form and structural results we discuss below, the non-parametric results indicate underweighting of others’ information: the slope of guesses against one’s own signal is steeper.

We first replicate the main finding from Experiment 1: Figure 5 shows that participants are 87% and 58% less sensitive to their partner’s information in the *Discussion* and *Informed* rounds, respectively, and we can reject  $\beta^o = \beta^p$  with  $p < 0.01$ .<sup>38</sup> In addition, though not all differences are statistically significant, participants underweight their partner’s information in *every* other treatment.

Most strikingly, participants are less sensitive to their partner’s signals even in the *Observe* treatment, in which they see their partner drawing balls from the urn with their own eyes while sitting beside them. Participants are 41% less sensitive to their partner’s information than to their own in this treatment ( $p = 0.04$ ). This result rules out a large set of confounds, including distrust of information communicated by others, perceived skill differences, order effects, and subtle differences in how information is communicated. Instead, it suggests that the act of producing information (i.e., physically drawing balls from the urn) or associating one piece of information with oneself as opposed to with one’s partner may be driving factors. We explore these mechanisms further in Experiment 3.

The remaining treatments provide further evidence of our core result that participants put less weight on their partner’s information than on their own. When participants learn their partner’s signals before drawing their own signals, in the *Reverse Order* treatment, they are still 53% less sensitive to their partner’s information ( $p = 0.04$ ). While still sizable, the effects in the *Draw-by-Draw* and *No First Guess* treatments are somewhat less pronounced at 38% ( $p = 0.18$ ) and 43% ( $p = 0.12$ ), respectively. The latter two estimates are not statistically significant, given the lower-than-intended sample size, but the difference in point estimates is roughly comparable across all six treatments, and we cannot reject that it is the same in all treatments ( $p = 0.82$ ).

The under-sensitivity to others’ information is also not meaningfully affected by the size of the incentives for accurate guessing (Appendix Figure A.V and Table A.IV). In particular, we see no significant change in underweighting in rounds that were randomly assigned to have 50% higher stakes, and in fact relative underweighting is somewhat higher with high stakes (52% versus 42%).

The structural estimates (Table 4 Panel B) paint a similar picture, with partici-

---

<sup>38</sup>To conserve space, in all rounds except the *Discussion* round, we focus in the main text on only the pre-discussion guesses, after the participant is informed of their partner’s draws by the experimenter. Figure A.IV shows reduced-form results for the post-discussion guesses (except for in the *Observe* round in which there was no discussion and thus no post-discussion guess), which look broadly similar to those for the pre-discussion guesses.

pants putting significantly less weight on their partner’s information in every round. The weight participants put on their own information tends to be at or above the Bayesian benchmark of  $\beta^p = 1$ , while they tend to underweight their partner’s information (though, given the imprecision of these estimates, we typically cannot reject equality with the Bayesian benchmark). In particular, in the *Observe* round, participants place 60% less weight (0.91/1.51) on their partner’s information than their own ( $p < 0.01$ ).

## 6 Experiment 3: External Validity and Mechanisms

Experiment 3 is a large-scale, between-subjects online experiment with three goals. First, we test the external validity of our findings with higher-education participants from a different cultural context. Second, it further investigates mechanisms. We test for the importance of (i) visual salience and presentation of information; and (ii) taking an action to generate one’s own signals; versus (iii) passively receiving information with labels indicating ‘ownership’ in causing lower sensitivity to others’ information. Third, we develop a simple online design that allows our experimental paradigm to be easily adopted by other researchers.

The experiment has additional strengths, such as a large sample size of almost 4,500 participants, which yields precise estimates even with a simple between-subjects design. We chose this larger sample size to be powered for smaller expected effect sizes given that online experiments tend to involve noisier decision-making and lower sensitivity to treatments than in physical lab studies (Gupta et al., 2021).

### 6.1 Recruitment and Sample

We recruited 4,489 participants from the US and UK on the online survey platform Prolific in February 2022, asking participants to complete a “short decision-making experiment” that involved a 15-minute survey. We required participants to have completed at least 50 previous surveys on Prolific with an approval rating above 95%. Participants were paid \$2.50 for completing the survey, plus up to \$2.80 as a bonus for accurate guessing. The resulting sample is similar in age and gender to our Experiment 1 and 2 samples (column 3 of Table 1). A key difference is that the sample is more highly edu-

cated, though participants’ task comprehension and performance are comparable across the three experiments.<sup>39</sup>

## 6.2 Experiment 3: Design

Participants recruited on Prolific were directed to a Qualtrics survey that embedded the experiment. Each participant was randomly matched to a partner.<sup>40</sup> The experiment had a purely between-subjects design, with participants randomized to one of the treatments—variants of the *Informed* condition—described below. Each participant played five identical rounds of the same treatment without feedback. We randomized across participants whether they drew their own signals first or instead first learned about their partner’s signals.<sup>41</sup>

***Informed of Partner’s Draws treatment*** ( $N = 1,008$ ). This treatment sought to emulate the *Informed* round from Experiments 1 and 2 as closely as possible in an online format. Participants saw a virtual urn and clicked to draw balls from it one at a time. The drawing and replacement of the balls from the urn was animated. Participants were shown a summary of their partner’s draws, as in the previous *Informed* treatments (e.g., “Your partner got to draw 5 marbles out of **the same** jar. They drew 1 red marble and 4 blue marbles.”).

***Observe Partner’s Draws treatment*** ( $N = 1,497$ ). This treatment (which we abbreviate to ‘*Observe*’) differed from the *Informed* treatment in that participants saw their partner’s draws being revealed using the same ball-by-ball animations as their own draws. The goal was to make the mode of presentation of the two sets of draws as similar as possible. Comparing the *Observe* and *Informed* treatments isolates the role of the presentation of others’ information, including its visual presentation and whether the information is delivered in summary form or signal-by-signal.

---

<sup>39</sup>In Experiment 3, we included eight multiple-choice comprehension questions asking participants to explain aspects of the instructions. Participants had to answer each question correctly before they could proceed. The average participant answered 92% of these questions on the first attempt, and more than 80% did so for all eight questions. The results are unchanged if we include only those who answered all questions correctly.

<sup>40</sup>Since the experiment did not include any direct communication between partners (as there was no *Discussion* round), it was not necessary for partners to be playing the game at the same time. Instead, we pre-generated the signals for each partner from the same ‘urn’.

<sup>41</sup>The script and a link to the online experiment are provided in Appendix C. Appendix Figure A.II Panel B illustrates the design of the different treatments. Selected screenshots showing how draws were presented to participants are reproduced in Appendix Figure A.VI.

**Labels Only treatment** ( $N = 1,487$ ). This treatment was the same as the *Observe* treatment, except that participants no longer had to click a button to generate each of their own draws. The only difference between one’s own and one’s partner’s signals was one word in the text that appeared below the animation (e.g., ‘Your first marble’ versus ‘Partner’s first marble’). If participants are less sensitive to their partner’s draws even in this minimal treatment, it implies that a subtle label is enough to generate a sense of ownership. In turn, comparing this treatment with the *Observe* treatment isolates the effect of taking an action to generate your own information. Taking action to generate information might be necessary to create a sense of ownership or to make that information more salient or vivid.

**Non-Rivalry treatment.** This treatment aimed to reduce any sense of competition with one’s partner. A randomly-selected half of the participants in the *Informed* treatment were truthfully informed that their partner would not be guessing the contents of the urn. Instead, the partner would only draw signals and be asked to remember them.

**Higher-Stakes treatment.** We randomized across participants the size of the incentives for accurate guessing. Half of those in each treatment earned a \$1.40 bonus minus \$0.20 cents times the absolute difference between their guess and the true number of red balls in the urn. For the other half of participants, the incentives were doubled.

**Survey.** After completing the five rounds of the experiment, participants completed a short survey. In the survey, without prior warning, we collected unincentivized measures of recall of their own and their partner’s draws from the last round as a measure of attention and memory. We also elicited participants’ perceptions of whether they used their own and their partner’s signals equally in informing their guesses.

### 6.3 Experiment 3: Results

To test whether participants are less sensitive to their partner’s information, we simply estimate equation (1) within each treatment condition and test  $\beta^o = \beta^p$ . Since the order of learning one’s own and one’s partner’s signals was randomized with equal probabilities, order effects do not confound this comparison. Figure 6 and Table 5 Panel A report the reduced-form results.<sup>42</sup>

---

<sup>42</sup>Appendix Figure A.III, Panel B, reports non-parametric results for Experiment 3, plotting participants’ guesses against their own signal and then against their partner’s. The pattern of results is similar to our reduced-form results, showing a greater responsiveness to own signal in the *Informed* and

In the *Informed* treatment, we qualitatively replicate our previous findings: participants are 17% less sensitive to their partner’s information than their own ( $p < 0.01$ ). The magnitude of this difference is sizable but notably smaller than in Experiments 1 and 2, as anticipated given the documented tendency for lower sensitivity to treatments in online experiments (Gupta et al., 2021). Intuitively, the sense that another person uncovered some of the information may be weaker in the online experiment since there is no interaction with this individual and the participant never sees them or learns anything about them. Similarly, the vividness and sense of ownership of one’s own signals may be weaker since the signals are not physically drawn by oneself but rather are generated by a computer and appear on the screen. Other differences such as a higher-education sample might also play a role, although we do not find stronger effects among lower-education participants within any of the three experiments (Table A.VI).

The design of Experiment 3 also permits an even simpler test of sensitivity to own and others’ information. Since participants were randomized to receive their own or their partner’s signals first, we can examine the *first* guess they make—after seeing only the first set of draws—and test whether this guess was less sensitive to draws made by their partner. Appendix Table A.V column 1 reports these results. Once again, we find that participants’ guesses are 17% less sensitive to their partner’s signal than to their own ( $p < 0.01$ ). Overall, these results provide strong evidence of lower sensitivity to others’ information even with a very different sample and experimental format.

In the *Observe* treatment, participants continue to be significantly less sensitive to their partner’s information ( $p < 0.01$ ). Indeed, the magnitudes are nearly identical to the *Informed* treatment (19% vs. 17%,  $p=0.74$ ). Consistent with the findings of Experiment 2, this suggests that differences in the presentation of own and others’ information do not explain the lower sensitivity to others’ information. Appendix Table A.V column 2 shows that this also holds for the first guess (10% lower sensitivity to others’ information,  $p < 0.01$ ).

By contrast, participants in the *Labels Only* treatment were only 4% less sensitive to their partner’s information, a difference that was not statistically significant in the reduced-form estimates ( $p = 0.27$ ). The difference in sensitivity to own and partner’s information ( $\beta^o - \beta^p$ ) is significantly lower in the *Labels Only* treatment than in the *Informed* ( $p = 0.02$ ) and *Observe* ( $p < 0.01$ ) treatments. We find a similar pattern in *Observe* treatments, but a more equal responsiveness in *Labels Only*.

the first guess (Appendix Table A.V column 3). We interpret this result as showing that taking an action to gather information—which, plausibly, generates a sense of ownership and/or increases the salience of the information—plays a role in producing greater sensitivity to it. Merely labeling information as ‘own’ versus ‘partner’s’ might not generate a sense of ownership when the participant receives the information passively.

The structural estimates presented in Table 5 Panel B again show clear evidence of underweighting of others’ information in the *Informed* and *Observe* treatments, by 31% and 33%, respectively (each  $p < 0.01$ ). Again, the difference in weights is significantly smaller in the *Labels Only* treatment compared to the *Observe* treatment ( $p=0.04$ ), implying that taking an action to generate one’s own draws increases the weight on own relative to others’ information. However, in contrast to the reduced-form estimates, the structural estimates show significant underweighting of partners’ information even in the *Labels Only* round ( $p<0.01$ ).<sup>43</sup>

**Stakes and awareness.** As in Experiment 2, the relative sensitivity to own vs. others’ information is not affected by the size of the incentives that participants faced for accurate guesses (Figure A.V, Panel B). For all three treatments, the differential sensitivity to own and partner’s signals is very similar (and statistically indistinguishable) between the low- and high-stakes groups. This finding suggests that participants are either unaware that they are less sensitive to others’ information or that they mistakenly believe it is optimal to discount others’ information. Consistent with the former interpretation, 77% of participants reported in the debriefing survey that they treated both pieces of information the same. Yet these same participants were 15% less sensitive to their partner’s information in the *Informed* treatment, nearly identical to the result in the full sample (Table A.VI Panel C).<sup>44</sup>

**Memory and attention.** We provide tentative evidence on whether up-front attention or imperfect memory mediate the under-sensitivity to others’ information (Appendix

---

<sup>43</sup>The structural estimates account for the full information content of the signal. For example, a person should place more weight on seeing 9 draws (5 red and 4 white) than on seeing just 1 red draw, whereas the reduced-form analysis treats these as identical (1 net red draw). The structural model also accounts for noisy choices and the fact that guesses are constrained to be between 4 and 16. These differences may explain the discrepancy in the reduced-form and structural analysis of the *Labels Only* treatment.

<sup>44</sup>14% instead reported using their own information more while 8% reported using their partner’s information more. In open-ended responses, participants who reported using their own information more often explained that this was because they (randomly) received more draws than their partners. A 10 percentage point increase in the share of draws received oneself is associated with a 12 percentage point increase in the likelihood of reporting using one’s own information more ( $p < 0.01$ ).

Figure A.VII and Table A.VII). In the debriefing survey, participants were asked to recall their own and their partner’s draws in the final round. Recall of one’s own draws was slightly higher on average (60% vs. 55%,  $p < 0.01$ ).<sup>45</sup> However, even when restricting the sample to those who perfectly remember *both* sets of draws, participants still place (marginally) significantly less weight on other’s information, by 9% (Appendix Figure A.VIII and Table A.VI Panel C), and we cannot reject that the difference in weights is the same in this subsample as in the overall sample ( $p = 0.75$ ). Thus, despite being able to recall others’ information when specifically asked to, participants fail to apply it to their choices in the same way that they do their own information.

**Competition.** Despite the incentives to make accurate guesses, one concern could be that participants underweight their partner’s information out of a sense of competitiveness; e.g., they may enjoy ‘winning’ by making good guesses precisely when their partner guesses poorly. This might plausibly lead to a strategy of ignoring the partner’s draws. However, the *Non-Rivalry* treatment—a sub-treatment of *Informed* in which the partner does not make any guesses—does not increase sensitivity to the partner’s signals (Appendix Figure A.IX and Table A.VIII).

## 7 Ruling out Potential Confounds

Our main finding is that people are more sensitive to information they uncover themselves compared to equally-relevant information uncovered by others, and that this is driven by failures of information aggregation rather than failures of communication. This result holds in three separate pre-registered experiments, when (i) participants can learn their partner’s information via a face-to-face discussion (Experiments 1 and 2); (ii) they are directly informed of their partner’s information by the experimenter (Experiments 1, 2, and 3); (iii) they observe their partner drawing balls from the urn with their own eyes (Experiment 2); (iv) the visual presentation of own and others’ information is identical (Experiments 2 and 3); and (v) the order of learning one’s own and others’ information is randomized or controlled for (Experiments 1 and 3). The result holds among participants who perfectly recall others’ signals and even among those who report using their

---

<sup>45</sup>The difference in recall is significant in all treatments, although it is smaller in the *Labels Only* treatment. Specifically, recall of own vs. partner’s draws in the different treatments are 64% vs. 56% for the *Informed* treatment, 60% vs. 55% for *Observe*, and 58% vs. 55% for *Labels Only*. We can reject equal memory gaps in the *Labels Only* and the *Informed* treatments ( $p=0.01$ ).

own and others' signals equally (Experiment 3).

Our findings cannot be explained by the possibility that participants find probabilistic reasoning difficult and generally deviate from Bayesian updating in systematic ways, for example by being conservative in belief updating, by overweighting small samples, or by neglecting base rates (Benjamin et al., 2019). Our empirical tests do not require participants to be Bayesian. Instead, they simply ask if information drawn oneself is treated similarly to identical information drawn by others. More generally, our results do not appear to be driven by simple confusion. They hold in both low-education samples in India and in high-education samples in the US and UK. Performance on comprehension questions was good, and we do not detect any significant within-experiment heterogeneity by comprehension scores or education (Appendix Table A.VI).

Another concern is that participants react less to their partner's information due to *distrust* of the communicated information. They might distrust what their partner tells them in the face-to-face discussion (despite the partner having incentives to share information) and or even distrust the message from the experimenter in the *Informed* condition (since the experimenter's incentives are unclear). However, several pieces of evidence suggest distrust of communicated information does not drive our results. First, watching one's partner drawing balls from the urn with one's own eyes, while being seated beside them, still results in lower sensitivity to the partner's draws (Experiment 2). Second, in Experiment 3, both one's own and one's partner's draws are simply displayed on the computer screen, such that it is not clear why one would trust draws assigned to oneself more. Finally, people report treating their own and their partner's information the same despite being less sensitive to their partner's information (Experiment 3). People therefore do not appear to explicitly distrust others' information in that experiment.

Communicated information is often *presented* differently than information uncovered oneself. For example, people usually share their information or advice with others in summary form whereas one's own experiences may uncover information in piecemeal fashion. Such differences in presentation also do not explain our results, since directly observing others' draws as they are uncovered does not reduce under-sensitivity to them.

Factors such as *overconfidence* are also unlikely to explain our results. Specifically, confidence about one's ability to use information to make accurate guesses should not cause individuals to weight information differently based on the source, once they learn

that information. People would instead need to believe that they are especially skilled or lucky at drawing signals.

*Competitiveness* towards their partner also does not appear to explain our findings. Competing over the average accuracy of their guesses should cause participants to fully use all available information. Moreover, in a treatment in which the partner does not make any guesses, and merely draws balls, participants are still less sensitive to signals drawn by their partner (Experiment 3).

The experimental scripts also tried to avoid any *experimenter demand* effects to underweight others' information. The instructions repeatedly mentioned that participants' goal was just to guess the number of red balls in the urn, and that their and their partner's draws were coming from the same urn. Participants were asked to make guesses both after seeing their draws and after seeing the partner's draws, which might—if anything—suggest that the experimenter expects them to incorporate both sets of information. Next, the smaller/null effects in the *Labels Only* treatment argue against experimenter demand effects in Experiment 3 since the experimental scripts were otherwise identical. Finally, most participants explicitly report using their and their partner's draws equally, and yet these same participants nonetheless display under-sensitivity to their partner's signal (Experiment 3).

## 8 Conclusion

This paper presents evidence of a powerful and potentially far-reaching barrier to social learning: people place more weight on information gathered themselves than on information gathered by others. They discount information uncovered by another person when they can learn it via a conversation with that person, when a trusted third party shares the information, and even when they have seen it with their own eyes. This phenomenon appears robust: we find evidence of it across three experiments with very different study populations, cultural contexts, and experimental formats.

While precise and closely controlled, a weakness of our lab setting is that it is fairly abstract and with moderate stakes at best (up to about half a day's income in Experiments 1 and 2). An open question is to what extent similar findings will emerge in ecologically valid settings and with higher stakes. We speculate that the mechanism we identify may underlie documented failures of social learning, whether in information

cascade experiments (Weizsäcker, 2010), farmers learning more from their own plots than from neighbors (Duflo et al., 2020; Chandrasekhar et al., 2022), decision-makers under-using AI-based recommendations (Agarwal et al., 2024), or central bankers being sensitive to their own personal economic experiences beyond aggregate data (Malmendier et al., 2021). But underweighting of others’ information could play a role in numerous other settings where social learning is possible.

We document this phenomenon in teams of strangers. In Conlon et al. (2024), we find that the marital setting—learning from one’s spouse—appears to counteract the discounting of others’ information for women but not for men. Future work should study the underlying mechanisms behind these differences and, more generally, what types of social or work relationships and contexts shape how effectively people learn from each other. For example, do people learn better from friends or colleagues? How do social status hierarchies affect the weight placed on a person’s independent information?

We find a role for taking some action to obtain new information in generating our effects; merely labeling information as one’s own has a significantly smaller effect. Our interpretation is that taking an action to acquire information activates a feeling of ownership of this information or makes it more vivid or salient, which in turn leads people to be more sensitive to it. Future work should investigate what types of actions, efforts, or experiences that generate new information create—or fail to create—this effect in natural settings. This includes investigating situations where people exert effort to actively discover others’ information, for example, by seeking out those with experience or searching for information online.<sup>46</sup> Field evidence that compares weights people put on their own and others’ information in a variety of contexts is needed to better understand the relevance and real-world costs of this phenomenon.

---

<sup>46</sup>In Experiment 1, we do in fact measure a type of action taken to obtain information: whether participants explicitly ask their partner about their draws during the discussion. We find that participants who ask underweight their partner’s signal just as much as others (Appendix Table A.IX). While this variable is of course endogenous, this result suggests that the effect may not be simply about active information-seeking in general, but something more specific such as generating information yourself.

Figure 1: Experimental Design

**Panel A: Randomization of Rounds**

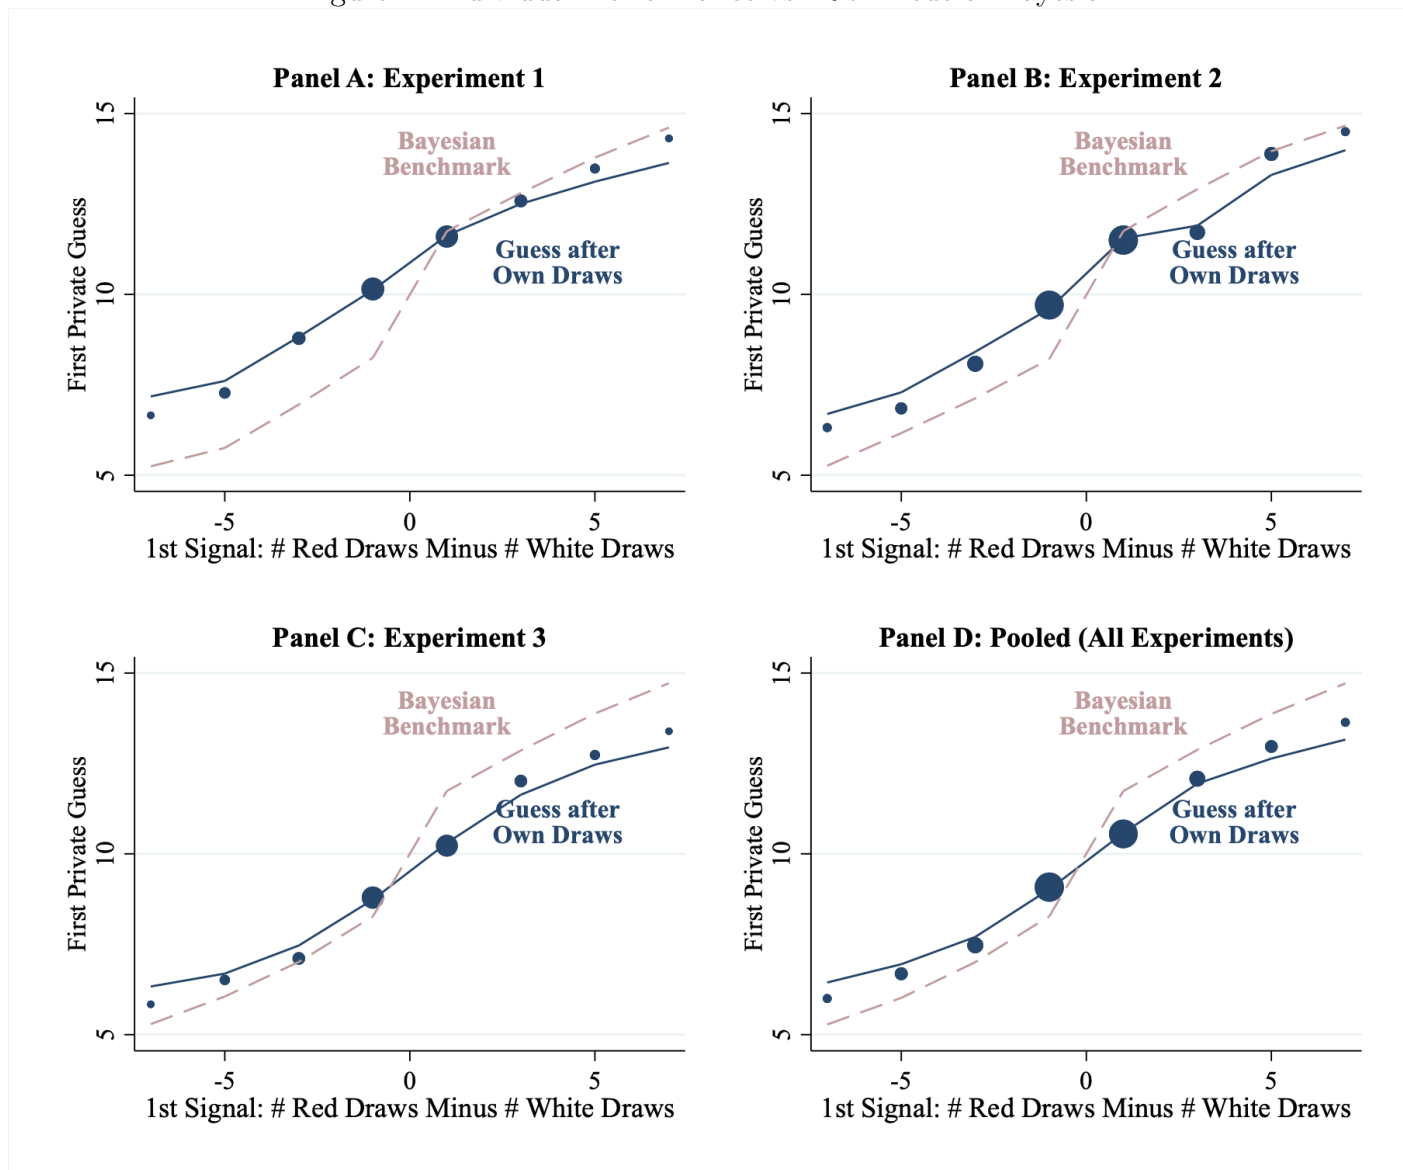

**Panel B: Structure of Individual, Discussion, and Informed Rounds**

**Panel A** shows the five rounds of Experiment 1. All participants get matched to a previously unknown partner and complete all five rounds with this partner (with the exception that in one randomly-selected *Discussion* round, participants were re-matched for that round only to generate variation in the relative gender of the partners. We do not exploit this variation in our paper). We randomized the order of the first two rounds (*Individual*, *Discussion*) and the order of the following three rounds: *Discussion*, *Informed of Partner's Guess*, and *Informed of Partner's Draws*.

**Panel B** describes the structure of the different rounds. In the *Individual* round, each participant gets two sets of private draws from the urn and makes a private guess after each set of draws. In the *Discussion* round, each participant makes one set of draws followed by a private guess. The two participants are then asked to discuss and make a joint guess before each makes a final private guess. The *Informed of Partner's Draws* round is identical to the *Discussion* round, except that pre-discussion, each participant is informed about their partner's first set of draws and then asked to make a private guess. In the *Informed of Partner's Guess* round (Appendix B.1), each participant is instead informed pre-discussion about their partner's first private guess and then asked to make a private guess.

Figure 2: Individual Performance vs. Risk-Neutral Bayesian

Notes: This figure plots participants' first private guess against the net number of red draws (red draws minus white draws) in participants' own first (private) signal. We only include observations where participants saw their own signal first (in Experiment 1, this is all observations). The blue solid curve shows locally weighted means (lowess). The pink dotted lines show the average of a risk-neutral Bayesian's guesses given the same signals. Dot size indicates number of observations for each net number of red draws. Panels A through C show data from each of the three experiments separately. Panel D shows pooled data from all three experiments.

Figure 3: Experiment 1: Non-Parametric Results

*Notes:* This figure shows average second private guess of participants in Experiment 1. The x-axis shows the net number of red draws (i.e., red draws minus white draws) in the second signal of the round. Dot size indicates number of observations for each net number of red draws. Lines show locally weighted means (lowess).

- In **Panel A**, the gray dots indicate average guesses in the *Individual* Round, where participants made the second set of draws themselves. The dark-blue dots in the graphs on the left show guesses in the *Discussion* Round, where the second set of draws had to be communicated to the participant via discussion.
- In **Panel B**, the lavender dots show average guesses in the *Informed of Partner's Draws* round, after the respondent is told of his/her partner's draws by the experimenter (but before the joint discussion).
- In **Panel C**, the lavender dots show average guesses in the *Informed of Partner's Draws* round after the joint discussion.

'F-test of equality' in the bottom right shows the  $p$ -value of a test of the joint hypothesis that the mean guess is equal across the two rounds at every value of net red draws.

Figure 4: Experiment 1: Reduced-Form Estimates

### Weights on Own vs. Others' Signals

Notes: This figure shows the weights participants put on different signals in Experiment 1. We estimate Equation (1) and then display  $\beta_2$  for each of the following four types of private guesses:

- (a) *Individual*, in which participants collect all information on their own. For this round, we report the coefficient on the net red draws in the participant's second set of draws, which replaces *Partner's Signal* in Equation (1);
- (b) *Discussion*, in which participants collect the first signal on their own and the second signal (their partner's) is only accessible via discussion;
- (c) *Informed of Partner's Draws (pre-discussion)*, where participants receive the second set of information directly from the experimenter but before any discussion with their partner;
- (d) *Informed of Partner's Draws (post-discussion)*, in which participants receive the second set of information directly *and* have the chance to discuss it with their partner.

For each of the dark-blue bars, we show the  $p$ -value of testing whether the weight in that round equals the corresponding weight in the *Individual* round (gray bar).

Figure 5: Experiment 2: Reduced-Form Estimates

39

*Notes:* This figure shows the weights participants put on different signals in Experiment 2. We estimate Equation (1) and then display  $\beta_1$  in gray and  $\beta_2$  in dark blue for each treatment. The dependent variable is participants' pre-discussion guess, except in the *Discussion* round. In the *Discussion* round, it is the post-discussion guess as there was no pre-discussion guess. In addition to the *Discussion* and *Informed of Partner's Draws* rounds, we look at the following treatments:

- (a) *Observe Partner's Draws*, in which each participant directly observes their partner's draws (as well as making their own);
- (b) *Draw-by-Draw*, in which participants receive the second set of signals directly one draw at a time;
- (c) *No First Guess*, in which participants receive their partner's signals (and their own) before making their first and only private guess;
- (d) *Reverse Order*, in which one participant receives their partner's signals first and makes their first private guess, and then receives their own signals and makes their second private guess.

For each round, we show the  $p$ -value of testing whether the weight on their signal ( $\beta_1$ ) equals the corresponding weight on their partner's signal ( $\beta_2$ ) in that round.

Figure 6: Experiment 3: Reduced-Form Estimates

Notes: This figure shows the weights participants put on different signals in Experiment 3. We estimate Equation (1) and then display  $\beta_1$  in gray and  $\beta_2$  in dark blue for each treatment.

- The first set of bars shows the weights participants put on signals in the *Informed of Partner's Draws* treatment, in which participants clicked to draw their own balls one at a time and were told their partner's number of red and white draws.
- The second set of bars represents the *Observe Partner's Draws* treatment, in which participants clicked to draw their own balls one at a time and directly observed their partner's draws appearing from the urn one at a time.
- The third set of bars corresponds to the *Labels Only* treatment, in which participants did not take any actions and instead passively observed their own and their partner's labeled draws one by one in the exact same format.

For each round, we show the  $p$ -value of testing whether the weight on their signal ( $\beta_1$ ) equals the corresponding weight on their partner's signal ( $\beta_2$ ) in that round.

Table 1: Sample Characteristics

	Experiment 1 (1)	Experiment 2 (2)	Experiment 3 (3)
Female	0.50 (0.50)	0.31 (0.46)	0.57 (0.50)
Age	34.66 (8.58)	38.40 (7.31)	37.70 (13.87)
Years Of Education	7.86 (3.94)	9.02 (3.49)	15.04 (2.03)
Expected Earnings (Relative to Bayesian)	0.82 (0.11)	0.84 (0.12)	0.89 (0.10)
Fraction of Comprehension Questions Correct	0.79 (0.14)	0.79 (0.13)	0.92 (0.13)
Number of Participants	500	293	4489

*Notes:* This table shows averages of key background characteristics for individuals in each of our three experiments. Standard deviations are in brackets. “Expected Earnings (Relative to Bayesian)” is calculated as the expected payoff of the participant’s guess given the draws they observed, divided by the expected payoff that the Bayesian risk-neutral guess (i.e., expected payoff-maximizing guess) would make given those same draws. “Fraction of Comprehension Questions Correct” shows the proportion of participants who correctly answer questions about the task (summary of questions in Table A.I).

Table 2: Experiment 1: Reduced-Form and Structural Estimates

N	500	1000	500	500

*Notes:* This table shows reduced-form and structural estimates for the weights on signals in Experiment 1. The dependent variable is participants' private guess. "Informed (Pre)" means the second private guess from the *Informed of Partner's Draws* round, after the participant was directly told their partner's signal but before the joint discussion. "Informed (Post)" means the third private guess, after the discussion. All standard errors are clustered at the pair (of two participants) level. Standard errors of the structural estimates are bootstrapped. \*, \*\*, and \*\*\* indicate significance at the  $p < 0.10$ , 0.05, and 0.01 levels of the difference  $\beta_2^p - \beta_2^o$ .

**Reduced-form coefficients:** Panel A shows reduced-form results, estimating Equation 1 by OLS. "Own First Signal" is the net number of red draws (i.e., red draws minus white draws) in the participant's first set of draws, which they drew themselves in all rounds. "Own Second Signal" is the net number of red draws in the participant's second set of draws in the individual round. "Partner's Signal" is the net number of red draws in the set of draws by the participant's partner, which was the second signal available to the participant in the *Discussion* and *Informed of Partner's Draws* rounds. All regressions include order fixed effects interacted with the participants' first and second signal.

**Structural parameters:** Panel B shows estimates of the structural model described in Section 3.3. "Own First Signal", "Own Second Signal" and "Partner's Signal" indicate the weights placed on the first set of signals, second set in the *Individual* round, and second (partner's) set in each other round in the agents' quasi-Bayesian updating rule.

Table 3: Experiment 1: Expected Earnings by Type of Guess and Number of Draws

	Individual	Discussion	Informed (Pre)	Informed (Post)
	(1)	(2)	(3)	(4)
$\gamma_1$ : # Own First Draws	1.51 (0.84)	2.26 (0.58)	3.12 (0.78)	2.46 (0.77)
$\gamma_2^o$ : # Own Second Draws	3.31 (0.90)			
$\gamma_2^p$ : # Partner's Draws		0.57 (0.61)	0.50 (0.78)	2.10 (0.80)
Constant	102.45 (5.37)	105.32 (4.44)	97.46 (6.09)	96.63 (5.88)
$\gamma_2^p - \gamma_2^o$		<b>-2.73***</b> <b>(1.02)</b>	<b>-2.81**</b> <b>(1.14)</b>	<b>-1.21</b> <b>(1.21)</b>
N	500	1000	500	500

*Notes:* This table compares participants' expected earnings in the *Discussion* and *Informed of Partner's Draws* rounds to their earnings in the *Individual* round. The table shows OLS estimates of the following equation for the *Discussion* and *Informed of Partner's Draws* rounds:

$$Expected\ Earnings_i = \alpha + \gamma_1 \# Own\ First\ Draws_i + \gamma_2^p \# Partner's\ Draws_i + \epsilon_i \quad (5)$$

and OLS estimates of the following equation for the *Individual* round:

$$Expected\ Earnings_i = \alpha + \gamma_1 \# Own\ First\ Draws_i + \gamma_2^o \# Own\ Second\ Draws_i + \epsilon_i \quad (6)$$

where  $Expected\ Earnings_{irt}$  is the expected earnings from  $i$ 's guess in the round in question, given the signals, and  $\# Own\ First\ Draws_i$  indicates the number of draws in the first set of signals, drawn oneself.  $\# Own\ Second\ Draws$  is the number of draws in the participant's second set in the *Individual* round and  $\# Partner's\ Draws$  is the participant's partner's number of draws, in the *Discussion* and *Informed of Partner's Draws* rounds. In estimation, we stack the estimating equations for all treatments and estimate them jointly, including controls for round order fixed effects. Standard errors are clustered at the pair level. \*, \*\*, and \*\*\* indicate significance at the  $p < 0.10$ , 0.05, and 0.01 levels of the difference  $\gamma_2^p - \gamma_2^o$ .

N	288	292	292	292	292	146

*Notes:* This table shows reduced-form and structural estimates for rounds in Experiment 2 (our second lab experiment).

**Reduced-form coefficients:** Panel A shows reduced-form results, estimating Equation 1 by OLS. The dependent variable is participants' private guess. "Informed" refers to the *Informed of Partner's Draws* round and "Observe" to the *Observe Partner's Draws* round. "Own Signal" indicates the net number of red draws (i.e., red draws minus white draws) in the participant's own set of draws. Similarly, "Partner's Signal" indicates the net number of red draws in their partner's set of draws. In estimation, we stack the estimating equations for all treatment and estimate them jointly. The joint regression also includes fixed effects for the order in which participants played treatment conditions, interacted with "Own Signal" and "Partner's Signal." Standard errors are clustered at the pair level. \*, \*\*, and \*\*\* indicate significance at the  $p < 0.10$ , 0.05, and 0.01 levels of the difference  $\beta_2^p - \beta_1$ .

**Structural parameters:** Panel B shows estimates of the structural model described in Section 3.3. "Own Signal" and "Partner's Signal" indicate the weights placed on their own and their partner's set of draws in the agents' quasi-Bayesian updating rule. Bootstrapped standard errors (clustered at the pair level) in parentheses. \*, \*\*, and \*\*\* indicate significance at the  $p < 0.10$ , 0.05, and 0.01 levels of the difference  $\beta_2^p - \beta_1$ .

Table 5: Experiment 3: Reduced-Form and Structural Estimates

	Informed (1)	Observe (2)	Labels Only (3)
<i>Panel A. Reduced Form Estimates</i>			
$\beta_1$ : Own Signal	0.52 (0.02)	0.53 (0.01)	0.48 (0.01)
$\beta_2^p$ : Partner's Signal	0.43 (0.02)	0.42 (0.01)	0.46 (0.01)
Constant	9.56 (0.04)	9.55 (0.03)	9.61 (0.03)
$\beta_2^p - \beta_1$	<b>-0.09***</b> <b>(0.02)</b>	<b>-0.10***</b> <b>(0.02)</b>	<b>-0.02</b> <b>(0.02)</b>
$p$ -value: $\beta_2^p - \beta_1$ same as in Informed		0.74	0.02
$p$ -value: $\beta_2^p - \beta_1$ same as in Observe			0.00
<i>Panel B. Structural Estimates</i>			
$\beta_1$ : Own Signal	0.49 (0.04)	0.51 (0.04)	0.46 (0.03)

$p$ -value: $\beta_2^p - \beta_1$ same as in Informed		0.52	0.25
$p$ -value: $\beta_2^p - \beta_1$ same as in Observe			0.04
N	5040	7485	7435

*Notes:* This table shows reduced-form and structural estimates for rounds in Experiment 3 (the online experiment).

**Reduced-form coefficients** Panel A shows reduced-form results, estimating Equation 1 by OLS. The dependent variable is participants' private guess. "Informed" refers to the *Informed of Partner's Draws* round and "Observe" to the *Observe Partner's Draws* round. "Own Signal" indicates the net number of red draws (i.e., red draws minus white draws) in the participant's own set of draws. Similarly, "Partner's Signal" indicates the net number of red draws in their partner's set of draws. Randomization was between participants in this experiment so we estimate the equation separately for each treatment condition. Standard errors are clustered at the pair level. \*, \*\*, and \*\*\* indicate significance at the  $p < 0.10$ , 0.05, and 0.01 levels of the difference  $\beta_2^p - \beta_1$ .

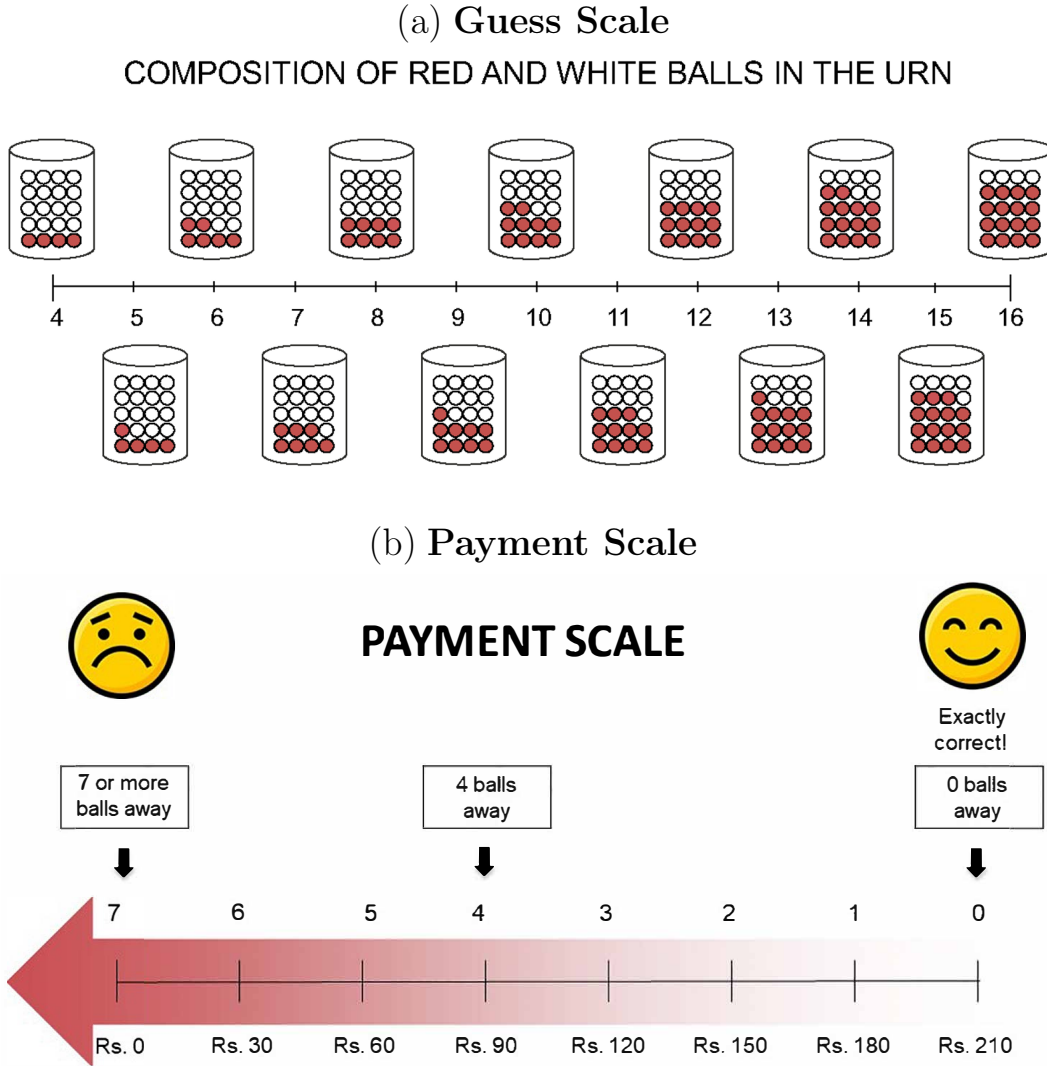

**Structural parameters:** Panel B shows estimates of the structural model described in Section 3.3. "Own Signal" and "Partner's Signal" indicate the weights placed on their own and their partner's set of draws in the agents' quasi-Bayesian updating rule. Bootstrapped standard errors (clustered at the pair level) in parentheses. \*, \*\*, and \*\*\* indicate significance at the  $p < 0.10$ , 0.05, and 0.01 levels of the difference  $\beta_2^p - \beta_1$ .

## A Supplementary Figures and Tables

### A.1 Supplementary Figures

Figure A.I: Visual Aids

*Notes:* This figure shows the visual aids used to explain the experiment to study participants in Experiment 1 and Experiment 2.

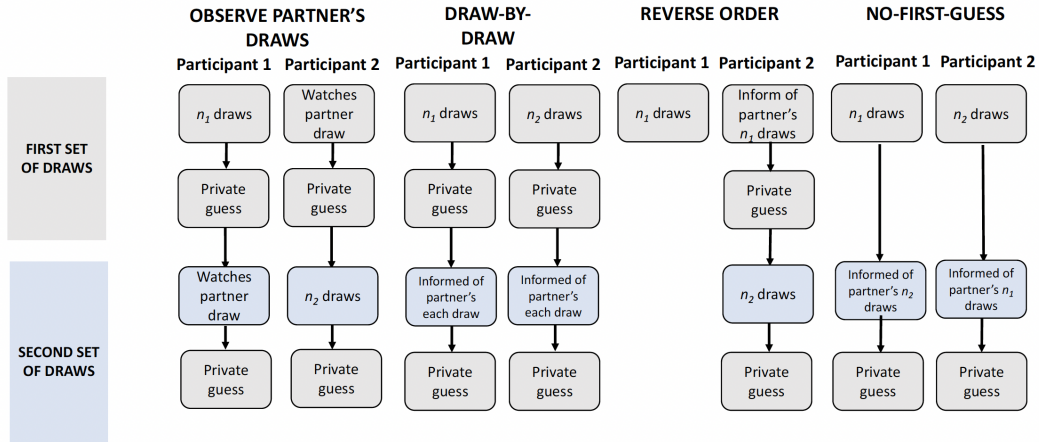

**Panel A:** The figure shows the scale which participants used to make their guesses. It shows the 13 possible urn compositions ranging from 4 to 16 red balls (among 20 balls in total). We induced common priors: participants were informed that in each round, each of these compositions was equally likely (probability  $1/13$  each). Participants guessed by placing a small token on top of the corresponding number.

**Panel B:** The figure shows the scale used to explain the incentives for accurate guessing to participants. For each pair of participants, one of their guesses was randomly selected to determine the pair's payment. In Experiments 1 and 2, on top of their participation fee, each individual receives an amount in Rupees (Rs.) equal to  $\max\{(105 - 15 \times |g - r|), 0\}$ , where  $g$  is the guess and  $r$  the true number of red balls for the randomly-selected guess. See more detail in Section 2.1.

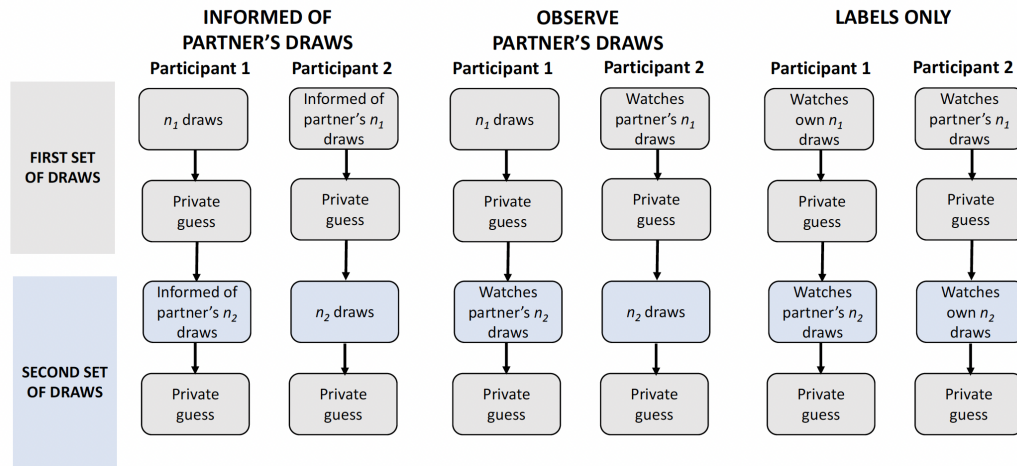

Figure A.II: Experimental Design for Experiment 2 and 3

**Panel A: Experiment 2**

**Panel B: Experiment 3**

**Panel A** describes the structure of the different rounds in Experiment 2. In addition to the *Discussion* and *Informed of Partner's Draws* rounds, participants played four variations of the *Informed of Partner's Draws* round. In the *Observe Partner's Draws* round, each participant makes one set of draws while their partner is present, followed by a private guess after each set of draws. The *Draw-by-Draw* round is the same as the *Informed of Partner's Draws* round except each participant is informed about their partner's draws one draw at a time. In the *Reverse-Order* round, one participant learns about their partner's draws first and makes a private guess, and then makes their own set of draws and makes another private guess. In this round, the treatment is only for one participant from the pair. The *No-First-Guess* round is the same as the *Informed of Partner's Draws* round except participants only make one private guess after both sets of draws.

**Panel B** describes the structure of the different rounds in Experiment 3. In this experiment, the participant's own information and partner's information was presented in the Qualtrics survey using a virtual urn. In the *Informed of Partner's Draws* round, each participant makes one set of draws followed by a private guess. They are informed of their partner's draws and asked to make another private guess. In this experiment, participants played two additional variations of the *Informed of Partner's Draws* round. The *Observe Partner's Draws* round is the same as the *Informed of Partner's Draws*, except each participant watches their partner's draws, followed by a private guess after each set of draws. The *Labels Only* round is identical to the *Informed of Partner's Draws* round, except participants watch both their own draws and their partner's draws, and make a private guess after each set of draws.

Figure A.III: Experiments 2 and 3: Non-Parametric Estimates

**Panel A: Experiment 2**

**Panel B: Experiment 3**

*Notes:* This figure shows the average second private guesses of participants in Experiment 2 and 3. In each graph, we plot this first against the participant's own signal (unconditional on partner's signal) in gray, and then again against their partner's signal (unconditional on own signal), in blue. The x-axis shows the net number of red draws (i.e. red draws minus white draws) in a given signal. Dots indicate average guesses, with dot size indicating number of observations, while the solid curves show locally weighted means (lowess). Because the signals are symmetrically distributed, equal weighting of own and others' information would imply the two curves should be equally steep. **Panel A** shows the average second private guess in Experiment 2. We show this for A.(i) *Informed of Partner's Draws*, where participants receive the second set of draws directly from the experimenter (and the second guess is before any discussion with their partner); and A.(ii) *Observe Partner's Draws*, where participants watch their partner drawing from the urn. **Panel B** shows the average second guess of participants in Experiment 3. We show results for: B.(i) *Informed of Partner's Draws*, where participants are given a summary of their partner's draws; B.(ii) *Observe Partner's Draws*, where participants watch their partner's draws appear from the urn; and B.(iii) *Labels Only*, where participants passively watch their own as well as their partner's draws appear from the urn.

Figure A.IV: Experiment 2: Reduced-Form Estimates

*Notes:* This figure shows the weights participants put on different signals when making their post-discussion private guess in Experiment 2. We estimate equation (1) and then display  $\beta_1$  in gray and  $\beta_2$  in dark blue for each treatment, except the *Observe Partner's Draws* round (in which there was no discussion and thus no post-discussion guess). In addition to the *Discussion* and *Informed of Partner's Draws* rounds, we look at the following treatments:

- (a) *Draw-by-Draw*, in which participants receive the second set of signals directly one draw at a time;
- (b) *No First Guess*, in which participants receive their partner's signals (and their own) before making their first and only private guess;
- (c) *Reverse Order*, in which one participant receives their partner's signals first and makes their first private guess, and then receives their own signals and makes their second private guess.

For each round, we show the  $p$ -value of testing whether the weight on their signal ( $\beta_1$ ) equals the corresponding weight on their partner's signal ( $\beta_2$ ) in that round.

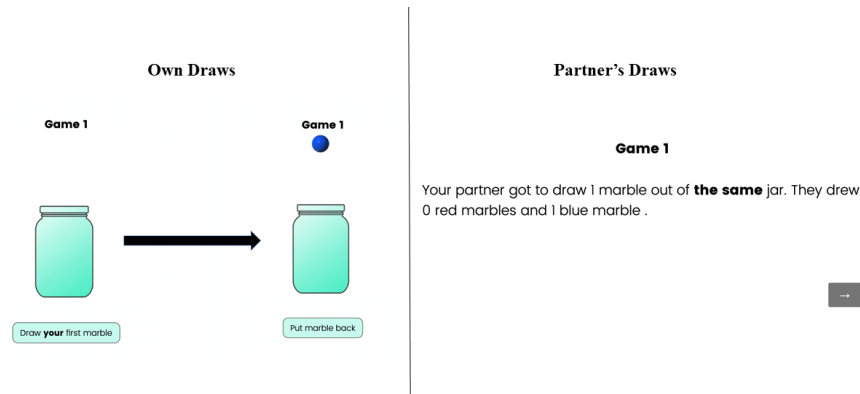

Figure A.V: Weights on Own vs. Others' Signals under Usual vs. Higher Stakes

*Notes:* This figure shows OLS estimates of equation 1 in Experiments 2 and 3, pooling the different treatments, separately by whether participants faced lower or higher stakes (incentives). Above each pair of bars, we show the  $p$ -value of testing whether the weight on own information (gray) equals the weight on partner's information (dark blue). The higher, centered  $p$ -value in each graph is the  $p$ -value of testing whether the difference in weights is the same in the usual and the high stakes condition. In both experiments, we cannot reject that it is.

Figure A.VI: Visual Presentation of Draws in Experiment 3

(a) Informed Of Partner's Draws

(b) Observe Partner's Draws

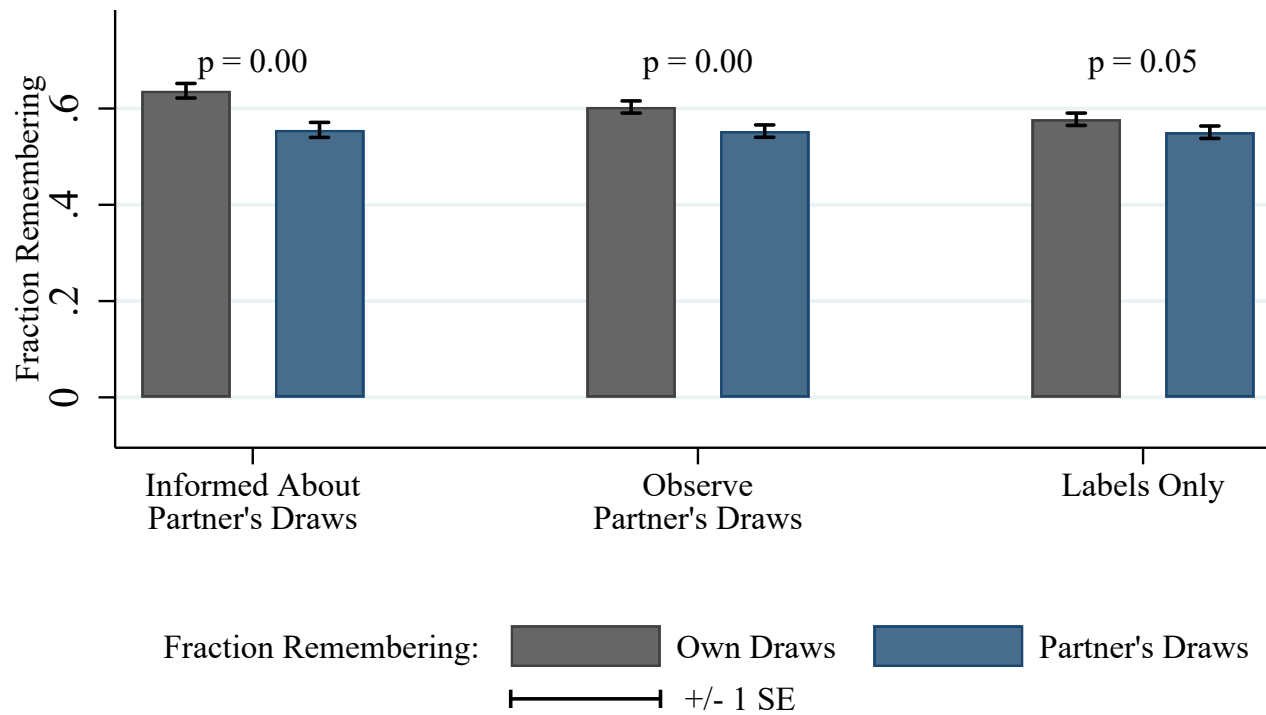

(c) Labels Only

*Notes:* This figure shows how the participant's own information and partner's information was presented in the Qualtrics survey for the different treatments in Experiment 3. The left panel of the figure shows how their own information was presented, and the right panel shows how their partner's information was presented. The arrows indicate subsequent screens. In all treatments, we emphasized that own and partner's draws were made from the same urn. **Panel A** shows how draws were presented in the *Informed of Partner's Draws* treatment. To obtain their own draws, participants clicked to draw balls one by one from a virtual urn, and after each ball was shown, clicked again to put it back in the urn, which was then animated to shuffle. In contrast, participants learned their partner's draws in summary form as shown in the right part of the panel. **Panel B** shows how draws were presented in the *Observe Partner's Draws* treatment. Participants obtained their own draws in exactly the same way as in the *Informed of Partner's Draws* round. For their partner's draws, participants were shown the same virtual urn and saw their partner's draws being revealed by the same ball-by-ball animation. However, the draws appeared one by one *without* clicking on the urn to obtain them. **Panel C** shows how draws were presented in the *Labels Only* treatment. The participants were shown a virtual urn and saw their own draws revealed by the same ball-by-ball animation, without having to click. Their partner's draws were revealed in exactly the same way.

Figure A.VII: Memory of Own vs. Others' Signals in Experiment 3

*Notes:* Participants in Experiment 3 were asked at the end of their final round (out of 5) if they remembered their own and their partner's draws—both number and color composition—from that round. The question was unannounced and unincentivized. This figure shows the fraction of participants correctly remembering their own (gray bar) versus their partner's (blue bar) draws in each treatment in Experiment 3. For each pair of bars, we show the  $p$ -value of testing that the same fraction remembered their own draws as remembered their partner's draws. See Table A.VII for the underlying numbers used in this figure.

Figure A.VIII: Weights on Own vs. Others' Signals for Participants Who Remember All Draws (Experiment 3)

*Notes:* Participants in Experiment 3 were asked at the end of their final round (out of 5) if they remembered their own and their partner's draws from that round. This question was unannounced and unincentivized. This figure shows OLS estimates of equation 1 in Experiment 3 for participants who correctly remembered both, pooling across treatments. The left pair of bars shows these participants' weights pooling all five rounds and the right set their weights in the final round only (i.e., the round for which they correctly remembered). Above each pair of bars, we show the  $p$ -value of testing whether the weight on own information (gray) equals the weight on partner's information (dark blue).

Figure A.IX: Experiment 3: Reduced-Form Estimates – Guessing vs. Non-guessing Partner in the *Informed* Treatment

55

*Notes:* This figure shows OLS estimates of equation 1 for participants in the *Informed of Partner's Draws* treatment in Experiment 3, separately by whether they were also assigned to the *Non-Rivalry* treatment, i.e., by whether their partner also guessed ('Guessing partner') or not ('Non-guessing partner'). For each of the dark-blue bars, we show the  $p$ -value of testing whether the weight on own information (gray bar) equals the weight on partner's information (blue bar). The higher, centered  $p$ -value is the  $p$ -value of testing whether the difference in weights is the same across the two treatments. We cannot reject that it is. See Table A.VIII for the underlying numbers displayed in this figure.

## A.2 Supplementary Tables

Table A.I: Comprehension and Memory

Question	Experiment 1	Experiment 2
<i>A. Basic Design</i>		
Number of balls	0.97	0.99
Colors of balls	1.00	1.00
<i>B. Common Prior</i>		
Possible < 4 red	0.93	0.96
Possible > 16 red	0.93	0.97
Who chooses number of red balls	0.81	0.84
Likelihood of each number	0.78	0.61
<i>C. Signals</i>		
Learn more from more balls	0.88	0.88
Possible have 4 draws	0.76	0.69
How number draws differs	0.47	0.47
How partner’s draws differ	0.61	0.63
<i>D. Incentives</i>		
Payment if 1 off	0.90	0.95
Payment if way off	0.85	0.92
Payment if 4 off	0.92	0.93
<i>E. Memory</i>		
Correctly remembered own guess	0.92	
Correctly remembered # of own draws	0.97	0.96
Correctly remembered # of own red draws	0.85	0.80
Correctly remembered # of partner’s draws		0.89
Correctly remembered # of partner’s red draws		0.70

*Notes:* This table shows summary statistics of participants’ comprehension of the task and their memory of previous draws and guesses. Column 1 shows the sample of 500 individuals of Experiment 1; and column 2 shows the sample of 292 individuals of Experiment 2. Panels A through D show the fraction of participants who answered each question correctly. For each question, we corrected the participant if they gave a wrong answer. Panel E shows the fraction of people who correctly remembered their own and their partner’s in some of the rounds.

- **Panel A** shows answers to questions “How many balls are in the urn?” (correct answer: 20), and “What colors are the balls?” (red and white).
- **Panel B** “Is it possible to have less than 4 /more than 16 red balls?” (no); “Who chooses how many balls are red?” (the computer), and “Are some numbers more likely than others?” (no).
- **Panel C** “Do you learn more from one draw or five draws?” (five); “Can you get exactly 4 draws in any round?” (no); “Will you have the same or different numbers of draws across rounds?” (could be same or different); “Will your partner have the same or different number to you?” (could be same or different).
- **Panel D** shows the fraction of people who could correctly indicate their payment on the scale if their guess was 1, 11, or 4 balls off.
- **Panel E** shows the proportion of participants who correctly remember their own guess and draws. “Correctly remembered own guess” correspond to the fraction of people who correctly remember their own guess in the *Informed of Partner’s Guess* round of Experiment 1. “Correctly remembered # of own draws” and “Correctly remembered # of own red draws” correspond to the fraction of people who correctly remember their own draws in the in the *Informed of Partner’s Draws* round in Experiment 1, and correspond to results pooled across 4 rounds, including the *Observe Partner’s Draws* round in Experiment 2. “Correctly remember # of partner’s draws” and “Correctly remembered # of partner’s red draws” correspond to the *Observe Partner’s Draws* round in Experiment 2.

Table A.I: (continued) Comprehension - Experiment 3

	<b>Experiment 3</b>
Goal of task	0.81
Number of balls	0.93
Possible numbers of red balls	0.97
Playing with partner	0.88
Drawing with replacement	0.90
Same urn as partner	0.91
Urn re-randomized across rounds	0.93
Incentive scheme	0.99

*Notes:* This continues Table A.I, showing summary statistics of participants' comprehension of the task in Experiment 3. Participants were asked 8 multiple-choice questions; if they got a question wrong, they had to retry until they got it right (they could re-read the relevant instruction). Shown are the fraction of participants answering each question correctly first time. The questions are shown below, with the correct answer in brackets.

- Goal of task – "What is the goal of the game you are playing today?" (To guess the number of red marbles in a virtual jar)
- Number of balls – "How many marbles are in the jar total?" (20)
- Possible numbers of red balls – "And how many red marbles could possibly be in the jar?" (Between 4 and 16 red marbles)
- Playing with a partner – "Who are you playing this game with?" (a real person who is taking the survey at about the same time with me). Note that in the *Non-rivalry* treatment, the correct answer was 'A real partner who is taking the survey at around the same time as me but doing a different task than what I'm doing'.
- Drawing with replacement – "Which of the following statements is correct: After each draw, the marble is not put back in the jar / After each draw, the marble gets put back and the contents get shuffled" (After each draw, the marble gets put back and the contents get shuffled)
- Same urn as partner – "Which of these statements is correct: My partner and I are drawing marbles from the same jar with the same number of red marbles / ... different number of red marbles / I am drawing marbles from the jar, and my partner is not / My partner is drawing marbles from the jar, and I am not" (My partner and I are drawing marbles from the same jar with the same number of red marbles)
- Urn re-randomized across rounds – "Which of these statements is correct: I will only play this game once / I will play this game 5 times with the contents of the jar always being the same / I will play this game 5 times with the contents of the jar being re-randomized each time" (I will play this game 5 times with the contents of the jar being re-randomized each time)
- Incentive scheme – "How can you affect the outcome of your bonus payment?" (For a randomly chosen guess, the closer I was to the true number of red marbles in the jar, the higher is my bonus)

Table A.II: Transcripts of Joint Discussions: Summary Statistics

	<b>Experiment 1</b>
Asked for Other’s Information	0.36
Explained Task to Partner	0.00
Shared Guess	0.29
Shared Number of Draws	0.19
Shared Composition of Draws	0.23
Suggested Final Guess	0.53
Length of Discussion (mins)	0.92

*Notes:* This table shows averages of key characteristics of the discussion among participants for Experiment 1. These variables were constructed using transcripts of the discussions between participants before the joint guesses were made. Except for the length of discussion, each variable is at the participant level (as opposed to at the pair level)

- We pool the discussions across 3 rounds, and exclude the *Individual* round and *Discussion* round with same-gender pairs. The latter was excluded due to challenges in identifying the two participants.
- “Shared Number of Draws” equals 1 if participants shared their total draws or mentioned the specific composition of their draws, (“I drew 4 red balls and 1 white ball”). “Shared Composition of Draws” equals 1 if participants shared the specific composition of draws (“I drew 4 red balls and 1 white ball”) or mentioned that they drew more of one color (“I drew more red balls than white”).
- 83% of our transcripts were audible, so the remaining have been excluded from this table.

Table A.III: Experiment 1: Error in Guess by Type of Guess and Number of Draws

	Individual (1)	Discussion (2)	Informed (Pre) (3)	Informed (Post) (4)
$\gamma_1$ : # Own First Draws	-0.13 (0.06)	-0.09 (0.04)	-0.09 (0.05)	-0.02 (0.05)
$\gamma_2^o$ : # Own Second Draws	-0.15 (0.07)			
$\gamma_2^p$ : # Partner's Draws		-0.04 (0.04)	0.02 (0.05)	-0.02 (0.06)
Constant	4.10 (0.46)	3.58 (0.32)	3.45 (0.45)	3.22 (0.46)
$\gamma_2^p - \gamma_2^o$		<b>0.11***</b> <b>(0.07)</b>	<b>0.17**</b> <b>(0.08)</b>	<b>0.14*</b> <b>(0.08)</b>
N	500	1000	500	500

*Notes:* This table compares the error in participants' guesses (the absolute difference between their guess and the true number of red balls in the urn) in the *Discussion*, *Informed of Partner's Draws*, and *Individual* round. The table shows OLS estimates of the following equation for the *Discussion* and *Informed of Partner's Draws* rounds:

$$|Guess - Truth|_{irt} = \alpha + \gamma_1 \# Own First Draws_i + \gamma_2^p \# Partner's Draws_i + \epsilon_i \quad (7)$$

and OLS estimates of the following equation for the *Individual* round:

$$|Guess - Truth|_{irt} = \alpha + \gamma_1 \# Own First Draws_i + \gamma_2^o \# Own Second Draws_i + \epsilon_i \quad (8)$$

where  $|Guess - Truth|_{irt}$  is the absolute value of difference between  $i$ 's guess and the true number of red balls in the urn in the round in question, and  $\# Own First Draws_i$  indicates the number of draws in the first set of signals, drawn oneself.  $\# Own Second Draws$  is the number of draws in the participant's second set in the *Individual* round and  $\# Partner's Draws$  is the participant's partner's number of draws, in the *Discussion* and *Informed of Partner's Draws* rounds. In estimation, we stack the estimating equations for all treatment and estimate them jointly including controls for round order fixed effects. Standard errors are clustered at the pair level. \*, \*\*, and \*\*\* indicate significance at the  $p < 0.10$ , 0.05, and 0.01 levels of the difference  $\gamma_2^p - \gamma_2^o$ .

Table A.IV: Weights on Own vs. Others' Signals under Usual vs. Higher Stakes

	Usual Stakes (1)	Higher Stakes (2)
<i>Panel A: Experiment 2</i>		
$\beta_1$ : Own Signal	0.62 (0.09)	0.59 (0.07)
$\beta_2^p$ : Partner's Signal	0.36 (0.08)	0.28 (0.06)
Constant	10.47 (0.12)	10.44 (0.11)
$\beta_2^p - \beta_1$	<b>-0.26**</b> (0.13)	<b>-0.30***</b> (0.11)
<i>p</i> -value: $\beta_2^p - \beta_1$ equal across treatments		<b>0.66</b>
<i>N</i>	1602	1602
<i>Panel B: Experiment 3</i>		
$\beta_1$ : Own Signal	0.50 (0.01)	0.51 (0.01)
$\beta_2^p$ : Partner's Signal	0.43 (0.01)	0.45 (0.01)
Constant	9.56 (0.03)	9.58 (0.03)
$\beta_2^p - \beta_1$	<b>-0.08***</b> (0.02)	<b>-0.06***</b> (0.02)
<i>p</i> -value: $\beta_2^p - \beta_1$ equal across treatments		<b>0.55</b>
<i>N</i>	9770	10190

*Notes:* This table shows OLS estimates of Equation 1 separately by whether participants faced usual or higher stakes (incentives). This table reports the same estimates as Figure A.V. \*, \*\*, and \*\*\* indicate significance at the  $p < 0.10$ , 0.05, and 0.01 levels of the difference  $\beta_2^p - \beta_1$ .

Table A.V: Experiment 3: Sensitivity of First Guesses to Own vs Other’s Signal

	Informed (1)	Observe (2)	Labels Only (3)
$\beta_1$ :First Signal $\cdot \mathbb{1}(\text{Own})$	0.66 (0.02)	0.67 (0.02)	0.61 (0.02)
$\beta_2^p$ :First Signal $\cdot \mathbb{1}(\text{Partner's})$	0.55 (0.02)	0.59 (0.02)	0.63 (0.02)
Constant	9.45 (0.04)	9.52 (0.03)	9.64 (0.03)
$\beta_2^p - \beta_1$	<b>-0.11***</b> <b>(0.03)</b>	<b>-0.07***</b> <b>(0.03)</b>	<b>0.02</b> <b>(0.03)</b>
$p$ -value: $\beta_2^p - \beta_1$ same as in Informed		0.68	0.01
$p$ -value: $\beta_2^p - \beta_1$ same as in Observe			0.01
N	5040	7485	7435

Notes: This table shows reduced-form results, estimating the following equation by OLS:

$$FirstGuess_i = \alpha + \beta_1 \cdot First\ Signal_i \cdot \mathbb{1}(\text{Own}) + \beta_2^p \cdot First\ Signal_i \cdot \mathbb{1}(\text{Partner's}) + \epsilon_i$$

where the dependent variable  $FirstGuess_i$  is participant  $i$ 's first private guess (before seeing the second signal).  $First\ Signal_i$  indicates the net number of red draws (i.e., red draws minus white draws) in the first signal that the participant saw,  $\mathbb{1}(\text{Own})$  is a dummy variable indicating whether this was  $i$ 's own signal, and  $\mathbb{1}(\text{Partner's})$  is a dummy variable indicating whether this was  $i$ 's partner's signal. "Informed" refers to the *Informed of Partner's Draws* round and "Observe" to the *Observe Partner's Draws* round. Standard errors are clustered at the pair level. \*, \*\*, and \*\*\* indicate significance at the  $p < 0.10$ , 0.05, and 0.01 levels of the difference  $\beta_2^p - \beta_1$ .

Table A.VI: Heterogeneity

	Comprehension:		Education:		Performance Belief:	
	Below median (1)	Above median (2)	Below median (3)	Above median (4)	Below median (5)	Above median (6)
<i>Panel A: Experiment 1</i>						
$\beta_1$ : Own Info	0.47 (0.04)	0.52 (0.04)	0.41 (0.04)	0.58 (0.04)	0.50 (0.04)	0.49 (0.06)
$\beta_2^p$ : Partner's Info	0.26 (0.04)	0.32 (0.04)	0.28 (0.04)	0.30 (0.04)	0.30 (0.04)	0.27 (0.05)

<i>p-val.</i> : $\beta_2^p - \beta_1$ equal	<b>0.15</b>		<b>0.82</b>			
<i>Panel C: Experiment 3</i>						
					Remember	Say Treat
					All Draws	Same
$\beta_1$ : Own Info	0.45 (0.01)	0.54 (0.01)	0.48 (0.01)	0.53 (0.01)	0.68 (0.02)	0.53 (0.01)
$\beta_2^p$ : Partner's Info	0.36 (0.01)	0.48 (0.01)	0.41 (0.01)	0.46 (0.01)	0.62 (0.02)	0.45 (0.01)
$\beta_2^p - \beta_1$	<b>-0.08***</b> (0.02)	<b>-0.06***</b> (0.01)	<b>-0.08***</b> (0.02)	<b>-0.06***</b> (0.02)	<b>-0.06*</b> (0.03)	<b>-0.08***</b> (0.01)
<i>p-val.</i> : $\beta_2^p - \beta_1$ equal	<b>0.36</b>		<b>0.61</b>			

This table shows estimates of Equation 1 estimated on subsets of the data. Columns 1 and 2 show estimates by whether comprehension (the percentage of comprehension questions answered correctly first time) is above or below median. The median was 79% in Experiments 1 and 2, and 100% in Experiment 3 (so 'above median' means everyone who got all questions right). Columns 3 and 4 show estimates by whether years of education is above or below median. Columns 5 and 6 show in Panel A estimates by whether the guesser's belief about their own performance – specifically, how much they expected their guesses to earn on average – is above or below median. This was only asked about in Experiment 1. In Panel C, column 5 restricts the Experiment 3 data to the final round of the experiment and to participants who correctly remember both their own and their partner's draws (asked after the round ended), while column 6 restricts the Experiment 3 data to participants who answered in a debriefing question at the end of the survey that they “treated my draws and my partner's draws the same.” For each pair of columns, “*p-val.*:  $\beta_2^p - \beta_1$  equal” is the *p*-value from testing the hypothesis that  $\beta_2^p - \beta_1$  is the same in each subsample. The data pools all treatments except the *Individual* round in Experiment 1. Standard errors in parentheses. \*, \*\*, and \*\*\* indicate significance at the  $p < 0.10$ , 0.05, and 0.01 levels of the difference  $\beta_2^p - \beta_1$ .

Table A.VII: Memory of Own vs. Others' Draws in Experiment 3

	Informed (1)	Observe (2)	Labels Only (3)
Fraction Remembering:			
Own Draws	0.64 (0.02)	0.60 (0.01)	0.58 (0.01)
Partner's Draws	0.56 (0.02)	0.55 (0.01)	0.55 (0.01)
p-val.: Equal memory of own and partner's	0.00	0.00	0.05
$N$	2016	2994	2974

*Notes:* Participants in Experiment 3 were asked at the end of their final round (out of 5) if they remembered their own and their partner's draws – both number and color composition – from that round. This question was unannounced and unincentivized. This table shows the fraction of participants correctly remembering their own versus their partner's information in each treatment in Experiment 3. In each column we show the  $p$ -value of testing whether the fraction remembering own and partner's draws is the same within that treatment. Standard error of the mean in parentheses. This table reports the same estimates as Figure A.VII.

Table A.VIII: Experiment 3: Reduced-Form Estimates – Rivalry

	Partner also guesses (1)	Partner doesn't guess (2)
$\beta_1$ : Own Signal	0.49 (0.02)	0.55 (0.02)
$\beta_2^p$ : Partner's Signal	0.43 (0.02)	0.43 (0.02)
Constant	9.54 (0.07)	9.59 (0.06)
$\beta_2^p - \beta_1$	<b>-0.06*</b> <b>(0.03)</b>	<b>-0.12***</b> <b>(0.03)</b>
<b><math>p</math>-value: <math>\beta_2^p - \beta_1</math> equal across treatments</b>		<b>0.17</b>
$N$	2525	2515

*Notes:* This table shows OLS estimates of Equation 1 for participants in the *Informed of Partner's Draws* treatment in Experiment 3, separately by whether their partner also guessed or did not guess (the *Non-Rivalry* treatment). This table reports the same estimates as Figure A.IX. The bottom row shows the  $p$ -value of testing whether the difference in weights is the same across the two treatments. Standard errors in parentheses. \*, \*\*, and \*\*\* indicate significance at the  $p < 0.10$ , 0.05, and 0.01 levels of the difference  $\beta_2^p - \beta_1$ .

Table A.IX: Experiment 1: Reduced-Form Results by Whether Participants Asked for Their Partner’s Draws (*Discussion* Round)

	Asked for Partner’s Draws (1)	Did not ask for Partner’s Draws (2)
$\beta_1$ : Own Signal	0.61 (0.08)	0.47 (0.07)
$\beta_2^p$ : Partner’s Signal	0.26 (0.10)	0.31 (0.08)
Constant	10.86 (0.22)	11.41 (0.22)
$\beta_2^p - \beta_1$	<b>-0.36**</b> <b>(0.15)</b>	<b>-0.16</b> <b>(0.12)</b>
<i>p</i> -value: $\beta_2^p - \beta_1$ equal		<b>0.32</b>
<i>N</i>	141	207

*Notes:* This table shows OLS estimates of Equation 1 for the *Discussion* treatment in Experiment 1, separately by whether participants asked their partner anything about their draws during the discussion. The bottom row shows the *p*-value of testing whether the difference in weights on own and partner’s signals is the same in both cases. Standard errors in parentheses. \*, \*\*, and \*\*\* indicate significance at the  $p < 0.10$ , 0.05, and 0.01 levels of the difference  $\beta_2^p - \beta_1$ .

## B Supplementary Information

### B.1 *Informed of Partner's Guess Round in Experiment 1*

The *Informed of Partner's Guess* round in Experiment 1 is identical to the *Informed of Partner's Draws* round, except that instead of sharing with each person the number of balls of each color their partner drew, the surveyor shares their partner's guess and the total number of draws (1, 5, or 9) on which that guess was based. Figure A.X shows estimates for the *Individual*, *Discussion*, and *Informed of Partner's Guess* rounds. The results look similar to those for the *Informed of Partner's Draws* round. People strongly discount their partner's information relative to their own in both the pre-discussion and post-discussion guesses. This could be explained by differential processing of own compared to others' information, but also by other (potentially rational) reasons, such as mistrust of partners' guesses or the increased computational difficulty of backing out what the partner's information must have been given their guess. Table A.X shows the corresponding reduced-form and structural estimates, which confirm the visual impressions from Figure A.X.<sup>47</sup>

---

<sup>47</sup>Note that the structural estimates assume that participants are able to back out from their partner's guess what their information must have been. Less weight on the partner's information could therefore reflect not just intrinsic discounting of others' information but also the extent to which this is a difficult problem for participants to solve (or one they do not attempt to solve).

Figure A.X: Experiment 1: Reduced Form Estimates – Informed of Partner’s Guess Round

### Weights on Own vs. Others' Signals

Notes: This figure shows the weights participants put on different signals in Experiment 1. We estimate Equation (1) and then display  $\beta_2$  for each of the following four types of private guesses:

- (a) *Individual*, where participants collect all information on their own. For this round, we replace *Partner's Info* in Equation (1) by the net red draws in the participant's second set of signals;
- (b) *Discussion*, in which participants collect the first set of information on their own and the second set (their partner's) is only accessible via discussion;
- (c) *Informed of Partner's Guess (pre-discussion)*, where participants have learned their partner's guess and number of draws directly from the experimenter but before any discussion with their partner;
- (d) *Informed of Partner's Guess (post-discussion)*, where participants have learned their partner's guess and number of draws *and* had the chance to discuss it with their partner.

For each of the dark-blue bars, we show the *p*-value of testing whether the weight in that round equals the corresponding weight in the *Individual* round (gray bar).

Table A.X: Reduced-Form Estimates in the Informed of Partner’s Guess Round

	Individual	Discussion	Informed (Pre)	Informed (Post)
	(1)	(2)	(3)	(4)
$\beta_1$ : Own First Signal	0.43 (0.06)	0.56 (0.06)	0.50 (0.10)	0.40 (0.10)
$\beta_2^o$ : Own Second Signal	0.52 (0.07)			
$\beta_2^p$ : Partner’s Signal		0.24 (0.07)	0.08 (0.09)	0.16 (0.08)
Constant	10.71 (0.16)	10.73 (0.16)	10.58 (0.22)	10.65 (0.22)
$\beta_2^p - \beta_2^o$		<b>-0.28***</b> <b>(0.08)</b>	<b>-0.45***</b> <b>(0.10)</b>	<b>-0.36***</b> <b>(0.10)</b>
N	500	1000	500	500

*Notes:* This table shows reduced-form estimates of Equation 1 for the *Individual*, *Discussion* and *Informed of Partner’s Guess* rounds in Experiment 1. The dependent variable is participants’ private guess. ‘Informed (Pre)’ means the second private guess from the *Informed of Partner’s Guess* round, after the participant was directly told their partner’s guess but before the joint discussion. ‘Informed (Post)’ means the third private guess, after the discussion. ‘Own First Signal’ is the net number of red draws (i.e., red draws minus white draws) in the participant’s first set of draws, which they drew themselves in all rounds. ‘Own Second Signal’ is the net number of red draws in the participant’s second set of draws in the individual round. ‘Partner’s Signal’ is the net number of red draws in the set of draws by the participant’s partner, which was the second signal available to the participant in the *Discussion* and *Informed of Partner’s Guess* rounds. All regressions include order fixed effects interacted with the participant’s first and second signal. All standard errors are clustered at the pair (of two participants) level. \*, \*\*, and \*\*\* indicate significance at the  $p < 0.10$ , 0.05, and 0.01 levels of the difference  $\beta_2^p - \beta_2^o$ .

## B.2 Comparing Structural to Non-Structural Results

In this section we consider whether the estimates of the structural model outlined in Section 3.3 are consistent with the main non-structural results presented elsewhere in Section 4.3. To do so, we simulate, using the estimates of the parameters of the model, what guesses participants in Experiment 1 would make given the signals they had. To eliminate unnecessary noise, instead of simulating just once for each guess of what the participant would choose (which is noisy), we calculate the expected guess. We then produce a version of Panel A of Table 2 using the simulated data. The question these analyses allow us to answer is, “Are the estimated biases from the structural model sufficient to explain the patterns found in the reduced-form and non-structural results?” If the model implied that the non-structural analyses would look very different than in fact they do, this would suggest that the model is not capturing something important about the biases we document.

Panel A of Table A.XI replicates Panel A of Table 2, our main reduced-form results for Experiment 1. Panel B shows the same regressions but using the model-implied expected guesses as the dependent variable rather than participants’ true guesses. Note that these variables, because they are expectations rather than single draws from the distribution of guesses, are mechanically much less noisy than the actual guesses. However, as Table A.XI shows, the *size* of the coefficients are quite similar (i.e., comparing within column across panels). Our interpretation of these results is that the model estimates are sufficient to explain the pattern of results shown in the reduced-form analyses.

Figure A.XI compares the non-parametric results from Figure 3 with similar estimates using the model-simulated data. There are four panels, representing the *Individual* round, *Discussion* round, *Informed of Partner’s Draws* round (pre-discussion), and *Informed of Partner’s Draws* round (post-discussion). Each panel shows the estimates given the actual guesses that participants make (in gray) along with the model-simulated expected guesses (in blue). As expected, actual guesses are noisier, but the slopes of the curves are extremely similar within each panel, suggesting that the non-parametric and structural effect sizes are of comparable magnitude. Note that there is a slight bias in the actual data toward guessing more red balls in the urn, which the structural model by construction cannot deliver (as evidenced by the gray tending to lie above the blue curve).

Table A.XI: Comparing Reduced-Form to Structural Results

	Individual (1)	Discussion (2)	Informed (Pre) (3)	Informed (Post) (4)
<i>Panel A: Actual Guesses</i>				
$\beta_1$ : Own First Signal	0.43 (0.06)	0.56 (0.06)	0.56 (0.09)	0.36 (0.09)
$\beta_2^O$ : Own Second Signal	0.52 (0.07)			
$\beta_2^P$ : Partner's Signal		0.24 (0.07)	0.07 (0.09)	0.28 (0.09)
Constant	10.71 (0.16)	10.73 (0.16)	10.64 (0.23)	10.66 (0.23)
$\beta_2^P - \beta_2^O$		<b>-0.28***</b> <b>(0.08)</b>	<b>-0.45***</b> <b>(0.11)</b>	<b>-0.24**</b> <b>(0.10)</b>
<i>Panel B: Model-Implied Expected Guesses</i>				
$\beta_1$ : Own First Signal	0.41 (0.01)	0.48 (0.01)	0.54 (0.02)	0.38 (0.01)
$\beta_2^O$ : Own Second Signal	0.58 (0.02)			
$\beta_2^P$ : Partner's Signal		0.24 (0.01)	0.04 (0.01)	0.27 (0.01)
Constant	9.98 (0.03)	9.98 (0.02)	9.98 (0.03)	9.98 (0.03)
$\beta_2^P - \beta_2^O$		<b>-0.34***</b> <b>(0.02)</b>	<b>-0.54***</b> <b>(0.02)</b>	<b>-0.31***</b> <b>(0.02)</b>
	500	1000	500	500

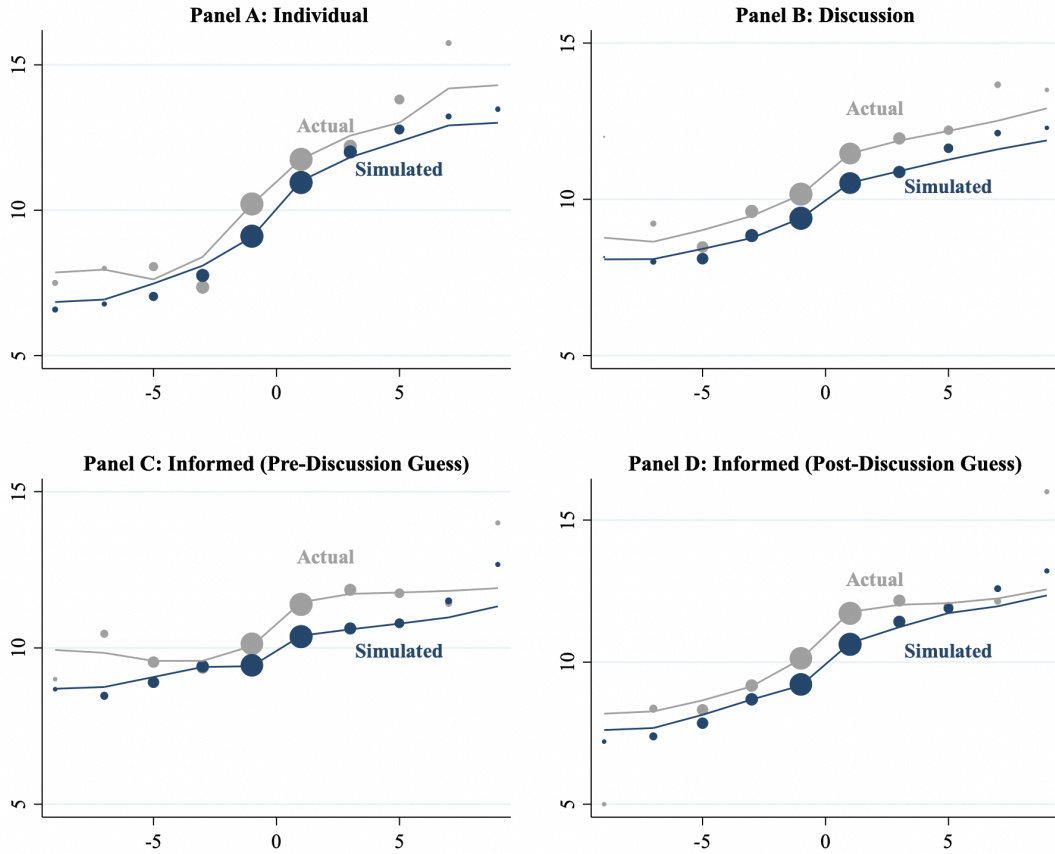

This table shows reduced-form weights on information in the Individual, Discussion and Informed of Partner's Draws rounds in Experiment 1. "Informed of Partner's Draws (Pre-Discussion)" means the dependent variable is the second private guess from the Informed of Partner's Draws round, after the participant was directly told their partner's information but before discussing it with their partner. "Informed of Partner's Draws (Post-Discussion)" means the dependent variable is the third private guess, after the discussion.

**Actual Guesses:** Panel A shows reduced-form results, estimating Equation 1 by OLS. The dependent variable is participants' actual private guess. "Own First Signal" is the net number of red draws (i.e., red draws minus white draws) in the participant's first set of signals, which they drew themselves in all rounds. "Own Second Signal" is the net number of red draws in the participant's second set of signals in the individual round. "Partner's Signal" is the net number of red draws in the set of signals drawn by the participant's teammate, which was the second set of signals available to the participant in the Discussion and Informed of Partner's Draws rounds. All regressions include order fixed effects interacted with the participant's first and second info.

**Model-Implied Expected Guesses:** show the same regressions as Panel A, but use the expected guesses (conditional on actual signals) implied by the structural estimates presented in Panel B of Table 2.

Figure A.XI: Simulated Guesses in Individual, Discussion, and Informed of Partner's Draws Rounds

*Notes:* This figure compares average actual guesses in Experiment 1 to the average *simulated* guess of participants using the structural model in Section 3.3. The x-axis shows the net number of red draws (i.e. red draws minus white draws) in the second signal of the round. The gray dots indicate average actual guesses, while blue dots indicate average simulated guesses. Panel A includes final private guesses in the *Individual* Round, where participants made the second set of draws themselves. Panel B includes final private guesses in the *Discussion* Round, where the second set of draws had to be communicated to the participant via discussion. Panel C includes the second private guesses in the *Informed of Partner's Draws* round, after the respondent is told of his/her partner's draws by the experimenter but before the joint discussion. Panel D includes final private guesses in the *Informed of Partner's Draws* round, after the joint discussion.

h
