I. Introduction

How small shocks are amplified and propagated through the economy to cause sizable fluctuations is at the heart of much macroeconomic research. Potential mechanisms that have been proposed range from investment and capital accumulation responses in real business-cycle models (e.g., Kydland and Prescott 1982) to Keynesian multipliers (e.g., Diamond 1982; Kiyotaki 1988; Blanchard and Kiyotaki 1987; Hall 2009; Christiano, Eichenbaum, and Rebelo 2011); to credit market frictions facing firms, households, or banks (e.g., Bernanke and Gertler 1989; Kiyotaki and Moore 1997; Guerrieri and Lorenzoni 2012; Mian, Rao, and Sufi 2013); to the role of real and nominal rigidities and their interplay (Ball and Romer 1990); and to the consequences of (potentially inappropriate or constrained) monetary policy (e.g., Friedman and Schwartz 1971; Eggertsson and Woodford 2003; Farhi and Werning 2013).

A class of potentially promising approaches based on the spread of small shocks from firms or disaggregated sectors through their economic and other links to other units in the economy has generally been overlooked, however. The idea is simple. A shock to a single firm (or sector) could have a much larger impact on the macroeconomy if it reduces the output of not only this firm (or sector), but also of others that are connected to it through a network of input-output linkages. The macroeconomic importance of this idea was downplayed by Lucas's (1977) famous essay on business cycles on the basis of the argument that if shocks that hit firms or disaggregated sectors are idiosyncratic, they would then wash out when we aggregate across these units and look at macroeconomic fluctuations—due to a law of large numbers-type

argument. Despite this powerful dismissal, this class of approaches has attracted recent theoretical attention. An important paper by Gabaix (2011) showed that when the firm-size distribution has very fat tails, so that shocks hitting the larger firms cannot be balanced out by those affecting smaller firms, the law of large numbers need not apply, opening the way to sizable macroeconomic fluctuations from idiosyncratic firm-level shocks.¹ Carvalho (2008), Acemoglu, Ozdaglar, and Tahbaz-Salehi (2015a, 2015b), Acemoglu et al. (2012), and Baqaee (2015) built on the multisector framework first developed by Long and Plosser (1983) to show how input-output linkages can also neutralize the force of the law of large numbers because shocks hitting sectors that are particularly important as suppliers to other sectors will not wash out and can translate into aggregate fluctuations.

One attractive aspect of these network-based approaches to the amplification and propagation of shocks is that they naturally lend themselves to an empirical analysis that can inform the importance of the proposed mechanisms, and the current paper undertakes such an empirical investigation. We are not the first to empirically study these interactions. One branch of existing research has provided model-based quantitative evaluation of the importance of these interactions (e.g., Horvath 1998, 2000; Carvalho 2008; Foerster, Sarte, and Watson 2011). A number of recent papers have instead focused on observable large shocks to a set of firms or industries and have traced their impact through the input-output network. Acemoglu et al. (2016) do this focusing on the spread of the impact of increased Chinese competition into the US economy through input-output linkages and local labor markets, though focusing on 10-year or 20-year effects. Boehm, Flaaen, and Nayar (2014), Barrot and Sauvagnat (2014), and Carvalho, Nirei, and Saito (2014) focus on the transmission of natural disasters, such as the 2011 Japanese earthquake, over the global input-output network.² Our paper contributes to this literature by studying the spread of four different types of shocks through the US input-output network at business-cycle frequencies. We also add to this by evaluating the contribution of the “geographic network” of industries—which measures the collocation patterns of industries across different commuting zones—to the interindustry propagation of macroeconomic shocks.³

We begin by developing some theoretical implications of the propagation of shocks through the input-output linkages. Most notably, theory predicts that supply-side (productivity) shocks propagate downstream much more powerfully than upstream—meaning that downstream cus-

tomers of directly hit industries are affected more strongly than their upstream suppliers. In contrast, demand shocks (e.g., from imports or government spending) propagate upstream—meaning that upstream suppliers of directly hit industries are affected more strongly than their downstream customers. This pattern results from the fact that supply-side shocks change the prices faced by customer industries, creating powerful downstream propagation, while demand-side shocks have much more minor (or no) effects on prices and propagate upstream as affected industries adjust their production levels and thus input demands. In the simplified benchmark model studied in much of the literature, where both production functions and consumer preferences are Cobb-Douglas (so that income and substitution effects cancel out), these effects emerge particularly clearly: there is no upstream effect from supply-side shocks and no downstream effect from demand-side shocks. In addition, we show that there is a restriction on the quantitative magnitudes of the own effect (measuring how a shock to an industry affects that industry) and the network effects.

Our empirical work focuses on four different types of industry-level shocks, all propagating through the input-output linkages at the level of 392 industries as measured by the Bureau of Economic Analysis input-output tables. Our four shocks are: (a) variation from the exogenous component of imports from China, (b) changes in federal government spending (affecting industries differentially on the basis of their dependence on demand from the federal government), (c) total factor productivity (TFP) shocks, and (d) knowledge/productivity stimuli coming from variation in foreign-industry patents. For each one of these shocks, we construct downstream and upstream network effects by using information from the input-output tables—namely by taking the inner product of the corresponding row or column of the input-output matrix with a vector of shocks at the industry level. We then estimate parsimonious models of industry-level value added, employment and productivity growth on their own lags, an industry's own shocks, and downstream and upstream effects from shocks hitting other industries.⁴

A brief summary of our results is as follows. For each one of these four shocks we find propagation through the input-output network to be statistically and economically important and broadly consistent with theory. In particular, for the two demand-side shocks—Chinese imports and federal government spending—we find that upstream propagation is substantially stronger than downstream effects, which are often zero

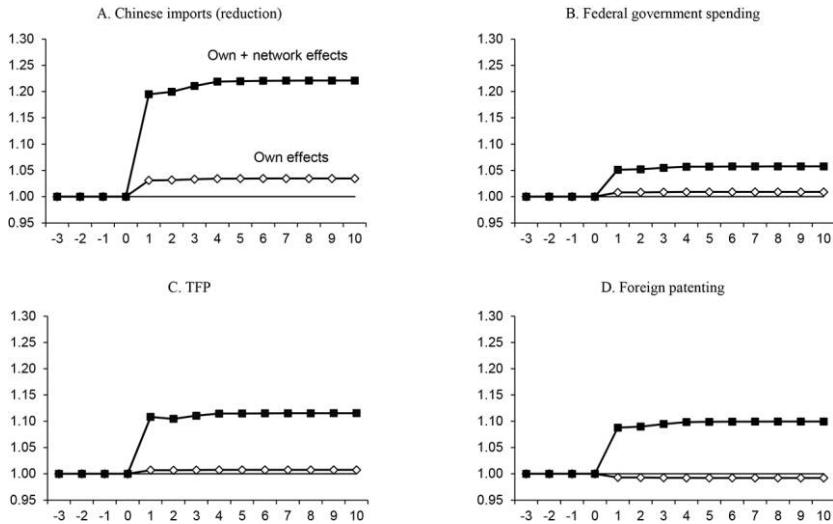

Fig. 1. Responses to a one standard deviation shock taken in isolation, value added
 Notes: Figure plots estimated response to a one standard deviation shock taken in isolation. Trade shocks are presented in positive terms to be visually comparable to the other shocks considered. Network effects focus on upstream contributions for the demand-side shocks of trade and federal spending and downstream contributions for the productivity shocks of TFP and foreign patenting. Responses are measured through log growth rates per the estimating equation and translated into levels off of a base initial level of one. The lag structure for the dependent variables includes three lags.

or of opposite sign. In contrast, for the two supply-side shocks—TFP and foreign patenting—there is strong downstream propagation, and limited or no upstream effects. In addition, the quantitative restrictions between own effects and network effects implied by theory are often verified. We also find the general patterns to be quite robust to different weighting schemes, additional controls, longer time scales, different lag structures, and so on.

The quantitative network effects are sizable and typically larger than the quantitative impact of own shocks. Figure 1 gives an indication of the magnitude of network effects by graphing the impulse response functions that result from a one-time, one standard deviation shock to every manufacturing industry.⁵ The different panels show that network effects are more pronounced than own effects. For example, one standard deviation increase in imports from China will have a direct (own) effect of reducing value added growth by 3.46% in 10 years. Factoring

in the (upstream) network effects, the total impact of the same shock is a 22.1% decline in value-added growth. This implies a sizable “network multiplier” (defined as the size of the total impact relative to the direct impact of the shock) of $22.1 / 3.46 \simeq 6.4$. The implied employment multiplier is similar, approximately 5.9.

We finally consider the effect of geographic collocation (“overlay”) of industries. The geographic overlay of industries reflects the importance of localized networks, as industries with substantial exchanges frequently locate near each other to reduce transportation costs and facilitate information transfer (e.g., Fujita, Krugman, and Venables 1999).⁶ After deriving a theoretically motivated measure of how industry-level shocks should propagate through the geographic overlay of industries, we show that geographic effects add another dimension of network-based propagation. While our main results are robust to these additional controls for geographic patterns, which demonstrates that input-output networks are operating above and beyond localized factors like regional business cycles, the geographic network also turns out to be a powerful transmitter of shocks from one industry to others. In fact, even though our estimates of the spread of shocks across collocating industries are slightly less robust than our baseline results, the effects appear quantitatively as large or even larger.

Overall, we interpret our results as suggesting that network-based propagation, particularly but not exclusively through the input-output linkages, might be playing a sizable role in macroeconomic fluctuations, and certainly a more important one than typically presumed in modern macroeconomics.

The rest of the paper proceeds as follows. Section II presents the theoretical model on input-output networks and shock propagation. Section III describes our data and provides descriptive statistics. Section IV presents our empirical results, focusing exclusively on national input-output connections, and section V further adds to the geographic overlay. The last section concludes, while appendix A and online appendices B and C contain further results and omitted proofs.⁷

II. Theory

In this section, we develop some simple theoretical implications of input-output linkages, and then turn to a discussion of the macroeconomic consequences of the geographic concentration of industries in certain areas.

A. Input-Output Linkages

We start with a model closely related to Long and Plosser (1983) and Acemoglu et al. (2012), which will clarify the role of input-output linkages.

Consider a static perfectly competitive economy with n industries, and suppose that each industry $i = 1, \dots, n$ has a Cobb-Douglas production function of the form:

$$y_i = e^{z_i} l_i^{\alpha_i^l} \prod_{j=1}^n x_{ij}^{a_{ij}}. \quad (1)$$

Here x_{ij} is the quantity of goods produced by industry j used as inputs by industry i , l_i is labor, and z_i is a Hicks-neutral productivity shock (representing both technological and other factors affecting productivity). We assume that, for each i , $\alpha_i^l > 0$, and $a_{ij} \geq 0$ for all j (where $a_{ij} = 0$ implies that the output of industry j is not used as an input for industry i), and

$$\alpha_i^l + \sum_{j=1}^n a_{ij} = 1,$$

so that the production function of each industry exhibits constant returns to scale.⁸

As equation (1) makes clear, the output of each industry is used as input for other industries or consumed in the final good sector. Incorporating the demand from other industries, the market-clearing condition for industry i can be written as

$$y_i = c_i + \sum_{j=1}^n x_{ji} + G_i, \quad (2)$$

where c_i is final consumption of the output of industry i , and G_i denotes government purchases of good i , which are assumed to be wasted or spent on goods households do not directly care about. We introduce government purchases to be able to model demand-side shocks in a simple fashion.

The preference side of this economy is summarized by a representative household with a utility function

$$u(c_1, c_2, \dots, c_n, l) = \gamma(l) \prod_{i=1}^n c_i^{\beta_i}, \quad (3)$$

where $\beta_i \in (0, 1)$ designates the weight of good i in the representative household's preferences (with the normalization $\sum_{i=1}^n \beta_i = 1$), and $\gamma(l)$ is a decreasing (differentiable) function capturing the disutility of labor supply.

The government imposes a lump-sum tax, T , to finance its purchases. Denoting the price of the output of industry i by p_i , this implies $T = \sum_{i=1}^n p_i G_i$. Since its income comes only from labor, wl , the representative household's budget constraint can be written as

$$\sum_{i=1}^n p_i c_i = wl - T.$$

We focus on the *competitive equilibrium* of this static economy, which is defined in the usual fashion, so that all firms maximize profits and the representative household maximizes its utility, in both cases taking all prices as given, and the market-clearing conditions for each good and labor are satisfied. The amount of government spending and taxes are taken as given in this competitive equilibrium. We also choose the wage as the numeraire (i.e., set $w = 1$).

The Cobb-Douglas production functions in (1), combined with profit maximization, imply

$$\frac{p_j x_{ij}}{p_i y_i} = a_{ij}. \tag{4}$$

In preparation for our main results we will present, let \mathbf{A} denote the matrix of a_{ij} 's,

$$\mathbf{A} = \begin{pmatrix} a_{11} & a_{12} & \dots & & \\ a_{21} & a_{22} & & \ddots & \\ & & & & \\ & & & & a_{nn} \end{pmatrix}.$$

We also define

$$\mathbf{H} \equiv (\mathbf{I} - \mathbf{A})^{-1} \tag{5}$$

as the *Leontief inverse* of the input-output matrix \mathbf{A} , and denote its typical entry by h_{ij} .

Proposition 1. *The impact of sectoral productivity (supply-side) shocks on the output of sector i is*

$$d \ln y_i = \underbrace{dz_i}_{\text{own effect}} + \underbrace{\sum_{j=1}^n (h_{ij} - \mathbf{1}_{j=i}) \times dz_j}_{\text{network effect}}, \tag{6}$$

where h_{ij} is the ij -th element of \mathbf{H} (the Leontief inverse of \mathbf{A}), and $\mathbf{1}_{j=i}$ is the indicator function for $j = i$. This equation implies that in response to productivity shocks, there are no upstream effects (i.e., no effects on suppliers of affected industries) and only downstream effects (i.e., only effects on customers of affected industries).

Suppose $\gamma(l) = (1 - l)^\lambda$. Then the impact of government-spending (demand-side) shocks on the output of sector i is

$$\begin{aligned}
 d \ln y_i = & \underbrace{\frac{d\tilde{G}_i}{p_i y_i}}_{\text{own effect}} + \underbrace{\sum_{j=1}^n (\hat{h}_{ji} - \mathbf{1}_{j=i}) \times \frac{1}{p_j y_j}}_{\text{network effect}} \times d\tilde{G}_j \\
 & - \underbrace{\sum_{j=1}^n \hat{h}_{ji} \times \frac{1}{p_j y_j} \times \frac{\beta_j}{1 + \lambda} \times \sum_{k=1}^n d\tilde{G}_k}_{\text{resource constraint effect}}
 \end{aligned} \tag{7}$$

where $\tilde{G}_j = p_j G_j$ is nominal government spending on sector j 's output, \hat{h}_{ij} is the ij -th element of the Leontief inverse matrix $\hat{\mathbf{H}} = (\mathbf{I} - \hat{\mathbf{A}})^{-1}$, and $\hat{\mathbf{A}}$ is the matrix with entries given by $\hat{a}_{ij} = p_j x_{ij} / p_i y_j$ (i.e., sales from industry j to industry i normalized by sales of industry j). This implies that demand-side shocks do not propagate downstream (i.e., to customers of affected industries), only upstream (i.e., only to suppliers of affected industries).

This proposition is proved in appendix A. Equations (6) and (7) form the basis of our empirical strategy, and link the output of sector i to its own “shock,” dz_i , and to “shocks” hitting all other industries working through the input-output linkages of the economy. In particular, in equation (6), dz_i is the own shock, while $\sum_{j=1}^n (h_{ij} - \mathbf{1}_{j=i}) dz_j$ is the *network effect*. Notice that this expression includes the propagation of the own shock through the input-output linkages, $h_{ii} - 1$, together with the network effect, and then subtracts the own effect (via the indicator function $\mathbf{1}_{j=i}$ which takes the value 1 when $j = i$ and the value 0 otherwise), so as not to double count this direct effect.⁹ Similarly, in equation (7), $d\tilde{G}_i / p_i y_i$ is the own shock and $\sum_{j=1}^n (\hat{h}_{ji} - \mathbf{1}_{j=i}) (1 / p_j y_j) d\tilde{G}_j$ is the network effect.¹⁰ These equations have several important implications.

First, what matters for the network effects is not directly the entries of the input-output matrix, \mathbf{A} or $\hat{\mathbf{A}}$, but its Leontief inverse. The intuition is instructive about the workings of the model. For example, a negative productivity shock to industry j will reduce its production and increase its price. This will adversely impact all of the industries that purchase inputs from industry j . But this direct impact will be further augmented

in the competitive equilibrium because these first-round-affected industries will change their production and prices, creating indirect negative effects on other customer industries (“downstream effects”). The Leontief inverse captures these indirect effects.

Second, the network effects in response to the demand-side and supply-side shocks are rather different. For supply-side shocks, the network effect, $\sum_{j=1}^n (\hat{h}_{ij} - \mathbf{1}_{j=i}) dz_j$, implies that the impact goes downstream (and *not at all* upstream). For demand-side shocks, the network effect is given by the term $\sum_{j=1}^n (\hat{h}_{ji} - \mathbf{1}_{j=i}) (1 / p_j y_j) d\tilde{G}_j$, indicating upstream propagation—the \hat{h}_{ji} term signifies the spread of a shock to industries that are suppliers of the affected industries. Equation (7), in addition, includes the resource-constraint effect, the term $\sum_{j=1}^n \hat{h}_{ji} (1 / p_j y_j) [\beta_j / (1 + \lambda)] \sum_{k=1}^n d\tilde{G}_k$, which reflects the impact of government spending on the representative household’s budget constraint—the government spending, financed by taxes, leaves fewer resources for private consumption. The parameter β_j here captures the fact that the impact of the lower net income of the representative household on the consumption of sector j depends on the share of this sector in consumption, given by β_j . When $\gamma' = 0$ so that there is no labor-supply response and thus $\lambda = 0$, this impact is maximized. On the other hand, when there is a positive labor-supply response, this effect is partially offset by increased production across the economy. It is also worth noting that these effects are still propagated through the input-output matrix as shown by the \hat{h}_{ji} terms, because a decline in the consumption of good j causes sector j to cut production and its input purchases from other sectors, leading to the upstream transmission of the direct implications of the resource constraint.

The next two examples illustrate in greater detail why supply-side or productivity shocks propagate downstream, while demand shocks propagate upstream.

Example 1 (Downstream propagation of supply-side shocks). Consider an economy with three sectors, with the input-output network as shown in panel (A) of figure 2. Sector 1 is the sole customer of sector 2, sector 2 is the sole customer of sector 3, and sector 3 is the sole customer of sector 1. The sectoral production functions are therefore given as

$$y_1 = e^{z_1} l_1^{\alpha_1} x_{12}^{\alpha_{12}}, \quad y_2 = e^{z_2} l_2^{\alpha_2} x_{23}^{\alpha_{23}}, \quad \text{and} \quad y_3 = e^{z_3} l_3^{\alpha_3} x_{31}^{\alpha_{31}},$$

and are all assumed to satisfy constant returns to scale. It follows from Proposition 1 that sector 1’s output is:¹¹

$$d \ln y_1 = \frac{dz_1 + a_{12} dz_2 + a_{12} a_{23} dz_3}{1 - a_{12} a_{23} a_{31}}.$$

Fig. 2. Theoretical examples

This expression shows that sector 1's output depends on the shocks to all three sectors. However, this is purely because of the propagation of productivity (supply-side) shocks downstream. For example, sector 3's productivity shock, z_3 , affects y_1 not because of upstream propagation, but because of the chain of downstream propagation: sector 1 is a customer of sector 2, and sector 2 is a customer of sector 3. Indeed, the coefficient of z_3 in this expression, $a_{12}a_{23}$, illustrates this indirect effect. To see further that there is no upstream propagation, consider a modification of this input-output network as shown in panel (B) of figure 2, where the link between sector 2 and sector 3 is severed (i.e., $a_{23} = 0$). The output of sector 1 then becomes

$$d \ln y_1 = dz_1 + a_{12}dz_2,$$

with no impact from z_3 . This verifies that it was the indirect downstream transmission of sector 3's productivity shock that impacted sector 1. With the link between sectors 2 and 3 severed, this indirect transmission ceases, and there is no longer any impact of z_3 on sector 1. Had it been the upstream propagation of productivity shocks, we would have seen a similar dependence of sector 1's output on z_3 since the input linkage between these two sectors has not changed.

The intuition for why there are no economic effects working upstream through the input-output network—as shown in Proposition 1 and Example 1—is related to the Cobb-Douglas nature of the production functions and preferences. Any impact on upstream industries will depend on the balance of a quantity effect (less is produced in industry

j after an adverse productivity shock) and price effect (each unit produced in industry j is now more expensive). With Cobb-Douglas technologies and preferences from households, these two effects exactly cancel out.¹² Downstream propagation, on the other hand, is a consequence of the fact that an adverse productivity shock to a sector leads to an increase in the price of that sector’s output, encouraging its customer industries to use this input less intensively and thus reduce their own production. This downstream propagation is also the reason why the impact of a shock depends only on input-output linkages, and not on the consumption shares, the β_j ’s. The consumption shares influence the level of production in different sectors, but not the proportional responses to productivity shocks; productivity shocks translate into proportional declines in prices and thus proportional downstream transmission, regardless of consumption shares.

The next example illustrates the propagation of demand-side shocks.

Example 2 (Upstream propagation of demand-side shocks). Consider again the economy depicted in panel (A) of figure 2, but now with government-spending shocks, expressed in nominal terms as $d\tilde{G}_1$, $d\tilde{G}_2$, and $d\tilde{G}_3$, rather than productivity shocks (and thus setting $dz_1 = dz_2 = dz_3 = 0$). We also set $\beta_1 = \beta_2 = \beta_3 = 1 / 3$. In this case, the change in the nominal output of sector 1 (with tildes again denoting nominal variables) can be derived as

$$d\tilde{y}_1 = \frac{1}{1 - a_{12}a_{23}a_{31}} \left\{ \begin{array}{l} d\tilde{G}_1 + a_{23}a_{31}d\tilde{G}_2 + a_{31}d\tilde{G}_3 \\ - \frac{(1 + a_{31} + a_{23}a_{31})}{3(1 + \lambda)} [d\tilde{G}_1 + d\tilde{G}_2 + d\tilde{G}_3] \end{array} \right\}.$$

Once again, shocks to all three sectors influence the nominal output of sector 1, but this time it is because of the cumulative indirect effects working upstream. In particular, the effect of the shock to sector 2, $d\tilde{G}_2$, on sector 1 is working upstream through its impact on sector 3 and then sector 3’s impact on sector 1, as can be seen from the fact that this term is multiplied by $a_{23}a_{31}$ in the first line. The resource constraint effect is shown in the second line. Similar to our analysis in the previous example, we can verify that the network effects shown in the first line are not working through downstream propagation by considering panel (B) of figure 2. When the link between sectors 2 and 3 is severed (or equivalently when $a_{23} = 0$), the change in the nominal output of sector 1 becomes

$$d\tilde{y}_1 = d\tilde{G}_1 + a_{31}d\tilde{G}_3 - \frac{(1 + a_{31})}{3(1 + \lambda)} [d\tilde{G}_1 + d\tilde{G}_2 + d\tilde{G}_3],$$

where the second term is again the indirect effect working through the household budget constraint. The absence of an impact from the government-spending shock to sector 2 now confirms that all propagation of demand-side shocks is upstream.

The intuition for why demand-side shocks propagate only upstream, as demonstrated in Proposition 1 and Example 2, is also instructive. With government-spending shocks, affected industries have to increase their production to meet the increased demand from the government. But given that they are using inputs from other supplier industries, this is only possible if industries supplying inputs to them also expand their inputs (proportionately to the role of these inputs in the production function of the affected industries). This is the logic for upstream propagation of demand-side shocks. Why is there no downstream propagation? Since all sectors have constant returns to scale, prices in this economy are entirely independent of the demand side. Government-spending shocks change quantities, but not prices (see appendix A). But this implies that the channel through which downstream propagation took place in response to productivity shocks—changing relative prices—is entirely absent, accounting for the lack of downstream propagation in response to demand-side shocks.

A *third* implication of equations (6) and (7) concerns the magnitudes of the coefficients of the own and network effects. The simplest way of seeing this is to reorganize these equations so that equation (6) becomes

$$d \ln y_i = h_{ii} \times dz_i + \sum_{j \neq i} h_{ij} \times dz_j,$$

which implies that if the indirect impacts of the own shock are included with the direct effect (and excluded from the network effect), then the coefficients of the own and the network effects, when properly scaled by the entries of the Leontief inverse, should be equal.¹³ The same is true for the demand-side shocks in equation (7), which can be rearranged as

$$d \ln y_i = \hat{h}_{ii} \frac{d\tilde{G}_i}{p_i y_i} + \sum_{j \neq i} \hat{h}_{ji} \frac{d\tilde{G}_j}{p_j y_j} - \sum_{j=1}^n \hat{h}_{ji} \frac{\beta_j}{1 + \lambda} \sum_{k=1}^n d\tilde{G}_k,$$

again showing the equality of the coefficients of the properly scaled own and network effects (the first two terms). These results readily extend to the employment equation by observing that the employment effects are derived from the output effects, and are thus proportional to them.

Fourth, equations (6) and (7) also imply that what matters in our theoretical framework are the contemporaneous shocks (e.g., dz_i), not some

future anticipated shocks.¹⁴ This motivates our use of current (or one-period lagged) shocks on the right-hand side of our estimating equations.

Finally, we further note that the implications of import shocks are also very similar to government-spending shocks, since a decline in imports (without imposing trade balance) is analogous to an increase in government spending on the same sectors, and for this reason we have not separately introduced these shocks in our theoretical model.

B. *The Effects of the Geographic Network*

Another important set of interlinkages, which could be represented as network effects, relates to geographic overlay over industries (corresponding to how industries collocate in various local labor markets, for example, as measured by commuting zones). Thinking through these geographic interactions is important to ensure that our empirical work can distinguish input-output network effects from these geographic interlinkages; moreover, these local linkages are also of direct interest as another transmitter of industry-level shocks.

Let us start with a simple reduced-form model capturing local demand effects

$$d \ln y_{r,i} = \eta \sum_{j \neq i} \frac{y_{r,j}}{y_r} d \ln y_{r,j} + dz_{i,r} \quad (8)$$

where $y_{r,i}$ is the output of industry i in region r , and $dz_{i,r}$ is an industry shock normalized to have a unit impact on the industry's output (in a region). In what follows, take η to be small (and in particular less than 1).

This equation captures the idea that if industries in a given region (local labor market) are hit by negative shocks, this will reduce economic activity and adversely affect output and employment in other industries, which is consistent with empirical evidence reported in Autor, Dorn, and Hanson (2013) and Mian and Sufi (2014). For example, if a large employer in a given local labor market shuts down, this will reduce the demand and thus employment and output of other local employers. The most obvious channel for this is through some local demand effects, though other local linkages would also lead to a relationship similar to (8).

The functional form in this equation is intuitive and implies that the impact of a proportional decline in industry j on industry i in the same region will be scaled by the importance of industry j in the region's output ($y_{r,j} / y_r$). Note also that, for simplicity's sake, we ignore the network effects coming from input-output linkages in this subsection.

The next step is to solve the within-region equilibrium implied by (8). Doing this with matrix algebra, we can write

$$d \ln y_{r,i} = (\mathbf{I} - \mathbf{B})^{-1} d\mathbf{z}_i, \tag{9}$$

where

$$\mathbf{B} = \begin{pmatrix} 0 & \eta(y_{r,2} / y_r) & \eta(y_{r,3} / y_r) & \dots & & \\ & 0 & & & & \\ & & 0 & & & \\ & & & 0 & & \\ & & & & 0 & \\ & & & & & 0 \end{pmatrix}.$$

Given our analysis of input-output models, it is not surprising that a Leontief inverse-type matrix is playing a central role here. But in this instance, it is useful for us to go beyond this matrix representation. In particular, when η is small as we have assumed, second- and higher-order terms in η can be ignored, and the within-region equilibrium can be expressed in the following form:¹⁵

$$d \ln y_{r,i} \approx dz_i + \eta \sum_{j \neq i} \frac{y_{r,j}}{y_r} dz_j.$$

Intuitively, this equation describes the within-region equilibrium as a function of shocks to all industries (solving out all “endogenous” terms from the right-hand side). Now using the fact that $d \ln y_{r,i} = dy_{r,i} / y_{r,i}$ and summing across regions, we obtain

$$dy_i = \sum_r dy_{r,i} \approx y_i dz_i + \eta \sum_r \sum_{j \neq i} \frac{y_{r,i} y_{r,j}}{y_r} dz_j,$$

which then enables us to obtain a simple representation of the geographic effects:

$$d \ln y_i \approx dz_i + \eta \sum_{j \neq i} \text{geographic_overlay}_{i,j} dz_j \tag{10}$$

where

$$\text{geographic_overlay}_{i,j} \equiv \sum_r \frac{y_{r,i} y_{r,j}}{y_i y_r}$$

is the noncentered cross-region correlation coefficient of industries i and j , normalized by their national levels of production, and represents their tendency to collocate.

Intuitively, this equation captures the fact that industries will be impacted not only by their direct shocks but also by the shocks of other

industries that tend to collocate with them. For example, if coal and steel industries are always in the same few regions, the steel industry will be negatively affected nationally not only when there is a negative shock to itself but also when there is a negative shock to the coal industry, because when the coal industry is producing less in the region, other industries in that region are also adversely affected, and steel is overrepresented among these industries that happen to be in the same region as coal.

Though the term we have for geographic overlay is simple and intuitive, it is based on an approximation that involves ignoring all terms that are second or higher order in η , thus posing the natural question of whether including some of these additional terms would lead to additional insights. To provide a partial answer to this question, we now include second-order terms (thus ignoring only third- or higher-order terms in η), which leads to a natural generalization of (10). In particular, the within-region equilibrium can now be expressed as

$$d \ln y_{r,i} \approx dz_i + \eta \sum_{j \neq i} \frac{y_{r,j}}{y_r} dz_j + \eta^2 \sum_{j \neq i} \frac{y_{r,j}}{y_r} \sum_{k \neq j} \frac{y_{r,k}}{y_r} dz_k.$$

Now summing across regions and repeating the same steps as above, we obtain

$$d \ln y_i = dz_i + \eta \sum_{j \neq i} \text{geographic_overlay}_{i,j} dz_j + \eta^2 \sum_{j \neq i} \sum_{k \neq j, i} \overline{\text{geographic_overlay}}_{i,j,k} dz_j$$

where the additional geographic overlay term, which includes triple collocation patterns, is

$$\overline{\text{geographic_overlay}}_{i,j,k} \equiv \sum_r \frac{y_{r,i} y_{r,j} y_{r,k}}{y_i y_j y_k}. \tag{11}$$

III. Data and Descriptive Statistics

This section describes our various data sources and the construction of the key measures of downstream and upstream effects and the geographic network.

A. Data Sources

Our core industry-level data for manufacturing come from the NBER-CES Manufacturing Industry Database (Becker, Gray, and Marvakov

2013). We utilize data for the years 1991–2009. Using the first change as a baseline, our estimations cover 17 changes from 1992–1993 to 2008–2009. In the first four changes, we have 392 four-digit industries; thereafter, we have 384 industries for 6,560 total observations. Though the theoretical predictions derived in the previous section are in terms of total industry output (shipments), our baseline analysis focuses on (real) value added due to its adjustment for energy costs, nonmanufacturing inputs, and inventory changes, which are all outside of our model. We show similar results using real and nominal shipments in appendix B.¹⁶

To construct our linkages between industries, we use the Bureau of Economic Analysis' 1992 Input-Output Matrix and the 1991 County Business Patterns database as described further below. In the next section, we describe the data used for each shock when introducing it.

B. *Upstream and Downstream Networks*

The construction of downstream and upstream effects follows Acemoglu et al. (2016). We construct the matrix \mathbf{A} introduced in section II from the 1992 "Make" and "Use" Tables of the Bureau of Economic Analysis. This matrix has input share entries corresponding to

$$a_{ij} \equiv \frac{Sales_{j \rightarrow i}}{Sales_i}.$$

As emphasized in section II, this quantity measures the total sales of inputs from industry j to industry i , normalized by the total sales (or equivalently the total costs) of industry i . Intuitively, it corresponds to how many dollars worth of the output of sector j (say tires) sector i (say the car industry) needs to purchase to produce one dollar's worth of its own output. When production functions are Cobb-Douglas, as we have assumed in our theoretical analysis, these input shares are constant regardless of prices. Equation (6) shows that network effects from supply-side shocks directly depend on these input shares. The Leontief inverse of the input-output matrix is then computed from the matrix of these input-output shares as $(\mathbf{I} - \mathbf{A})^{-1}$ to give our downstream network measure. In what follows, we use the notation $Input\%_{j \rightarrow i}$ to represent the elements of the Leontief inverse of the input-output matrix.¹⁷

For constructing the network effects from demand-side shocks, we again follow equation (7), which decomposes the response of a sector into an own effect, a network effect, and the resource-constraint effect.

We first ignore the last one and focus on the network effect. The presence of the \hat{h}_{ji} (or \hat{a}_{ji}) terms in this equation underscores the different aspects of input-output linkages involved in upstream propagation. The empirical counterparts of the \hat{a}_{ij} terms are

$$\frac{Sales_{i \rightarrow j}}{Sales_i} \equiv a_{ji} \frac{Sales_j}{Sales_i},$$

which we use to compute the upstream network measures. We use $Output\%_{i \rightarrow j}$ to represent these Leontief inverse terms. We return to the resource-constraint effect later.

C. Geographic Overlay

We also measure the geographic overlay of two industries using the metric developed in the theory section,

$$\text{geographic_overlay}_{i,j} \equiv \sum_r \frac{y_{r,i} y_{r,j}}{y_i y_j}.$$

We define regions through BEA commuting zones and utilize 1991 County Business Patterns data to measure the overlay. We also calculate the higher-order geographic overlay term (11). In practice, however, we observe very little additional explanatory power with the second metric and thus focus simply on the direct collocation case.

D. Correlation Matrices

Table 1A shows the correlation matrix of these interconnections, excluding own-industry interconnections (i.e., network diagonals). Upstream and downstream material flows are moderately correlated at 0.4 and somewhat less strongly correlated with geographic overlay, indicating that input-output linkages operate, for the most part, beyond common geographies.

Table 1B depicts the correlation of our four measures of shocks with each other and shows that our different shocks are only weakly correlated, assuaging concerns that we may be tracing the effects of omitted shocks when modeling the effect of each shock one at a time. Column (5) of table 1B reports the average between-industry correlation for each shock (e.g., how correlated is, say, the federal spending shock of an industry with the federal spending shocks of other industries). This is relevant in part because a high between-industry correla-

Table 1A
Correlation Matrix of Network Interconnections

	Downstream Leontief (1)	Upstream Leontief (2)	Geographic Overlay (3)
Downstream Leontief	1		
Upstream Leontief	0.400	1	
Geographic overlay	0.108	0.275	1

Notes: Downstream networks represent inputs from supplier industries into the focal industry's production, expressed as a share of the focal industry's sales (e.g., rubber inputs into the tire industry as a share of the tire industry's sales). Upstream networks represent sales from the focal industry to industrial customers, expressed as a share of the focal industry's sales (e.g., sales of tires to car manufacturers as a share of the tire industry's sales). Both networks are measured from the 1991 BEA Input-Output Matrix. Shares allow for flows to nonmanufacturing industries and customers and thus do not sum to 100% within manufacturing. Leontief connections provide the full chain of interconnections in the network matrix. Geographic overlay is measured as the sum across regions of the interaction of a focal industry's employment share in the region times the share of regional activity for other industries. Regions are defined through commuting zones and use 1991 industrial activity from the County Business Patterns database. Correlations are statistically significant at the 1% level.

Table 1B
Correlation Matrix of Shocks

	China Trade Shock (1)	Federal Spending Shock (2)	TFP Shock (3)	Foreign Patenting Shock (4)	Correlation Coefficient (5)
China trade shock	1				0.200
Federal spending shock	0.031	1			0.452
TFP shock	-0.021	0.017	1		-0.002
Foreign patenting shock	-0.023	0.030	0.003	1	0.003

Notes: Baseline trade shocks for manufacturing industries are the lagged change in imports from China relative to 1991 US market volume, following Autor et al. (2013). A negative value is taken such that positive coefficients correspond to likely beneficial outcomes, similar to other shocks. All trade analyses instrument US imports with the rise in Chinese imports in eight other advanced countries, and this table reports the correlation of the IV component. Baseline federal spending shocks for manufacturing industries are the lagged log change in national federal spending interacted with the 1992 share of sales from industries that went to the federal government. Baseline TFP shocks for manufacturing industries are the lagged log change in four-factor TFP taken from the NBER Productivity Database. Baseline patent shocks for manufacturing industries are the lagged log change in USPTO patents filed by overseas inventors associated with the industry. These correlations are presented after year fixed effects are removed from each shock. The Correlation Coefficient column presents the average pairwise correlation of the given shock series between any two industries.

tion of shocks might create spurious network effects in the presence of an omitted higher-order impact of own shocks. The relatively low between-industry correlations, except for the federal spending shock, are comforting in this regard. The higher between-industry correlation for the federal spending shock is unsurprising since it is constructed from the interaction of aggregate time-series variation in federal spending with a time-invariant measure of federal spending dependency of each industry (as detailed further below).

IV. Results: The Input-Output Network

This section provides our primary empirical results that quantify shock propagation through the input-output networks, leaving the analysis of the geographic network to the next section. We focus on four shocks: (a) import penetration, (b) federal spending changes, (c) TFP growth, and (d) foreign-patenting growth. The first two correspond to demand-side shocks, while the latter two are supply side, approximating productivity shocks. We first consider each shock by itself, describing how we measure it, and studying its empirical properties in isolation. After cycling through all four shocks independently, we jointly model them and provide an extended discussion of economic magnitudes.

A. Empirical Approach

Throughout, our main estimating equations are direct analogs of equations (6) and (7) in the theory section, and take the following form:

$$\Delta \ln Y_{i,t} = \delta_t + \psi \Delta \ln Y_{i,t-1} + \beta^{\text{own}} \text{Shock}_{i,t-1} + \beta^{\text{upstream}} \text{Upstream}_{i,t-1} + \beta^{\text{downstream}} \text{Downstream}_{i,t-1} + \varepsilon_{i,t}, \quad (12)$$

where i indexes industries, δ_t denotes a full set of time effects, $\varepsilon_{i,t}$ is an error term, and $Y_{i,t}$ stands for one of three industry-level variables from the NBER manufacturing database: real value added (using the industry's shipments deflator), employment, and real labor productivity (real value added divided by employment).

In our baseline results, time periods correspond to years. We start with a model that only considers the core regressors outlined in equation (12), and then we show robustness checks that add extra controls. We allow only a single lag of the dependent variable on the right-hand

side for parsimony. The role of additional lags is taken up in robustness checks.

The key regressors are $Shock_{i,t-1}$, the industry's own direct shock (taken from one of the four shocks introduced above), and $Upstream_{i,t-1}$ and $Downstream_{i,t-1}$, which stand for the shocks working through the network. These network shocks are always computed from the interaction of the vector of shocks hitting other industries and a vector representing the interlinkages between the focal industry and the rest (e.g., the row or the column of the input-output matrix); we provide exact details below.

The upstream and downstream terminology in network analyses has some ambiguity. In the remainder, we follow our usage in section II and label "upstream effects" as those arising from shocks to customers of an industry that flow up the input-output chain; in parallel, we describe "downstream effects" as those arising from shocks to suppliers of an industry that flow down the input-output chain. Henceforth, for clarity, we use "upstream" and "downstream" terms to describe exclusively the effects. When there is a need to describe where the shock originates, we will use the terms "customer" and "supplier" to avoid confusion.

Thus, we measure downstream effects (due to supplier shocks) and upstream effects (due to customer shocks) closely mimicking the theoretical equations, (6) and (7). In particular, these are given by the weighted averages of shocks hitting all industries using entries of the Leontief inverse matrices as weights:

$$Downstream_{i,t} = \sum_j (Input\%_{j \rightarrow i}^{1991} - \mathbf{1}_{j=i}) \cdot Shock_{j,t}, \quad (13)$$

and

$$Upstream_{i,t} = \sum_j (Output\%_{i \rightarrow j}^{1991} - \mathbf{1}_{j=i}) \cdot Shock_{j,t}, \quad (14)$$

where $\mathbf{1}_{j=i}$ is an indicator function for $j = i$, and the summation is over all industries, including industry i itself. Thus as in the equations (6) and (7), when computing the downstream effect for sector i , we take into account the indirect linkages from this industry to itself (e.g., the fact that industry i supplies to industry j , which is also a supplier to i), but we subtract the direct effect of the shock, since in our regressions we will directly control for the shock to sector i .

Several other points are worth noting. First, as already observed, input-output linkages (and thus the Leontief inverse entries) are predetermined and measured in 1991. Thus, downstream and upstream effects are simply a function of shocks in connected industries working through a predetermined input-output network.

Second, we lag both own and network shocks by one period, simply to avoid any concern about contemporaneous measurement issues from our dependent variables to shocks (e.g., in the case of TFP) and about contemporaneous joint determination. It should be stressed, however, that we do not claim that this timing will enable us to estimate causal effects. Rather, we rely on the plausible exogeneity of shocks, especially for imports from China and federal government spending, and caution that this exogeneity is likely to be absent in the case of the TFP and foreign-patenting shocks.

Third, equation (12) is formulated in changes, and shocks are always specified in changes as detailed below. The specification could have alternatively been written in levels together with an industry fixed effect. The advantage of the current formulation is that it both follows more directly from and connects to our theoretical model, and imposes that the error term is stationary in differences, which is generally a better description of macro time series.

Finally, in what follows, unless otherwise stated, we standardize the $Shock_{i,t-1}$ variable so that a unit increase corresponds to a one standard deviation change in the positive direction (e.g., decrease in imports or increase in TFP), and the $Upstream_{i,t-1}$ and $Downstream_{i,t-1}$ variables are constructed in the same units. This implies that the coefficient on the $Shock_{i,t-1}$ variable will measure the impact of a one standard deviation increase in the industry's own shock, whereas the coefficients on $Upstream_{i,t-1}$ and $Downstream_{i,t-1}$ will measure the impact of a one standard deviation increase in the shock of all customers and suppliers of an industry. Moreover, all of these coefficients are directly comparable and are expected to be positive where theory predicts a network-based effect.

B. China Import Shocks

Our first shock relates to the growth of imports from China and follows Autor et al. (2013) and Acemoglu et al. (2016). Acemoglu et al. (2016) show this pattern for decade-long adjustments, and we extend this analysis to shorter frequencies considered in macroeconomics. As highlighted in section II, this demand-side shock should have greater upstream effects than downstream effects, and in the case of Cobb-Douglas, downstream effects should not be present at all.

We first define *ChinaTrade* to capture this industry exposure to rising Chinese trade,

$$ChinaTrade_{j,t} = - \frac{\text{US Imports from China}_{j,t}}{\text{US market size}_{j,1991}}$$

This variable, however, is clearly endogenous, as it will tend to be higher when the industry in question has lower productivity growth for other reasons, creating greater room for a rise in imports, and is thus not a good measure of shocks for our analysis. To deal with this endogeneity concern, we follow Autor et al. (2013) and Acemoglu et al. (2016) and instrument this variable with its exogenous component, defined as the change in import penetration from China to eight major non-US countries relative to 1991 US market volume, with the nations being Austria, Denmark, Finland, Germany, Japan, New Zealand, Spain, and Switzerland:

$$ChinaTrade_{j,t}^{IV} = - \frac{\text{Non-US Imports from China}_{j,t}}{\text{US market size}_{j,1991}}$$

This instrument has the advantage of not being directly affected by changes in productivity or demand in the US economy.¹⁸

The downstream and upstream effects are calculated from (13) and (14) adapted to this case. For example, for the downstream effects coming from supplier industries, we model the shock:

$$Downstream_{i,t}^{Trade} = \sum_j (\text{Input}_{j \rightarrow i}^{1991} - \mathbf{1}_{j=i}) \cdot \Delta ChinaTrade_{j,t}. \quad (15)$$

We also construct the network instruments using the same reasoning as in (13) and (14). For example, for the downstream effects this simply takes the form of

$$Downstream_{i,t}^{TradeIV} = \sum_j (\text{Input}_{j \rightarrow i}^{1991} - \mathbf{1}_{j=i}) \cdot \Delta ChinaTrade_{j,t}^{IV}.$$

In summary, we have three endogenous variables, $ChinaTrade_{j,t}$, $Downstream_{i,t}^{Trade}$ and $Upstream_{i,t}^{Trade}$, and three instruments, $ChinaTrade_{j,t}^{IV}$, $Downstream_{i,t}^{TradeIV}$ and $Upstream_{i,t}^{TradeIV}$. The first stages for these three variables are shown in appendix table 1 (all appendix tables are included in appendix B).¹⁹

Table 2A presents our estimates of own and network effects from this exercise, using a table format that we replicate for each subsequent shock. Table 2A presents our baseline results for the three outcome variables, considering one and three lags for the dependent variable, and shows strong upstream effects on supplier industries (similar to Acemoglu et al. 2016).

More specifically, recall that we have standardized (in terms of standard deviation units) and normalized all of our shocks to be positive, so that an increase in imports from China corresponds to a negative value

Notes: Estimations consider network structures and the propagation of trade shocks. Baseline trade shocks for manufacturing industries are the lagged change in imports from China relative to 1991 US market volume, following Autor et al. (2013). A negative value is taken such that positive coefficients correspond to likely beneficial outcomes, similar to other shocks. Explanatory variables aggregate these industry-level components by the indicated network connecting industries. These network explanatory variables are expressed as lagged changes in nonlog values. Downstream and upstream flows use the Leontief inverse to provide the full chain of material interconnections within manufacturing. All trade analyses instrument the direct and network effects from US imports with the rise in Chinese imports in eight other advanced countries. Upstream = own test uses the exact formula discussed in the text and is calculated through unreported auxiliary regressions. Variables are winsorized at the 0.1% level and initial shocks are transformed to have unit standard deviation for interpretation. Estimations include year fixed effects, report standard errors clustered by industry, and are unweighted.

***Significant at the 1 percent level.

**Significant at the 5 percent level.

*Significant at the 10 percent level.

of the shocks, and thus positive coefficients imply that rising imports from China reduce value added and employment in the affected industries. In this light, the results in column (1) indicate that a one standard deviation own-industry shock reduces the focal industry's value-added growth by 3.4%.²⁰ More interestingly given our focus, they also indicate that a similar one standard deviation change in customers of an industry leads to a 7.6% decline in value-added growth through upstream effects. Downstream effects are of opposite sign and statistically insignificant, though they are sometimes quantitatively sizable. Lack of (same-signed) significant downstream effects in response to demand-side shocks is consistent with our main theoretical implications outlined in section II. Finally, the bottom row of the table tests the other implication from the theory highlighted in Proposition 1, that the relevant diagonal entry from the Leontief inverse matrix (i.e., the coefficient on $h_{ii} \cdot \Delta \text{ChinaTrade}_{i,t-1}$) should be equal to the upstream effect from other industries. For value added, this restriction is marginally rejected at 10%, though it is not rejected in any of the other columns.²¹

Column (2) shows that the overall pattern is similar when two more lags of the dependent variable are included on the right-hand side, even though these lags show some evidence of additional persistence. In particular, the quantitative implications are very similar, and it is again the upstream effects that are significant while the downstream ones are not.

Our regression specifications follow directly from Proposition 1 (for example, in the case of the China import shocks, equation [7]). The coefficient estimates in these regression equations do not directly translate into quantitative effects for “multipliers,” however. This is because the upstream effect (the relevant dimension of the network effects in this case) corresponds to the impact of the shock of all other industries, weighted by their upstream linkages, on the focal industry. Instead, to obtain an economically meaningful multiplier, measuring how large the total impact of a shock is relative to its direct effect, we need to measure its impact on *all other* industries. To achieve this, we convert upstream and downstream effects into a *weighted average* of shocks in other industries using the Leontief inverse elements of weights.²² We use these adjusted estimates to construct the impulse response functions depicted in figure 1 and for computing the relevant multipliers. Panel (A) of figure 1 depicts the impulse response of value added to a one standard deviation Chinese import shock obtained from this exercise (with a specification corresponding to column [2] of Table 2A). These impulse responses show that the quantitative magnitude of the network effects (in this

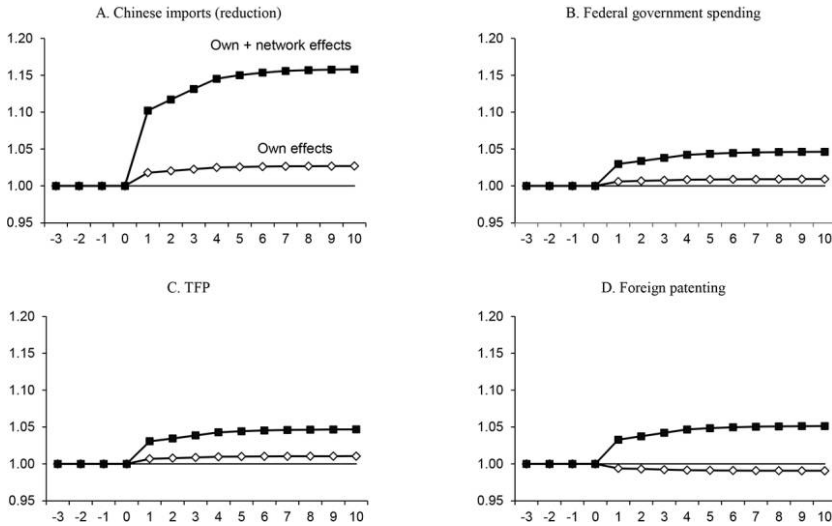

Fig. 3. Responses to a one standard deviation shock taken in isolation, employment
 Notes: See figure 1.

case, upstream effects, since we are focusing on demand-side shocks) are considerably larger than the direct effect: the direct effect (from the own shock) after 10 periods is a 3.46% increase in value-added growth, while the total impact is a 22.09% (3.46 + 18.64) increase in value added. This yields a multiplier of 6.4 ($\approx 22.09 / 3.46$), and implies that input-output linkages more than double the direct effects of demand-side shocks. It can be seen from the figure that the implied multipliers are very similar at different horizons.

Columns (3) and (4) turn to employment. The overall pattern and even the quantitative magnitudes are very similar, with clear upstream effects and no downstream effects, and the theory-implied restrictions receive support from our estimates. Panel (A) of figure 3 depicts the impulse response of employment to the same shock as in figure 1. The implied multiplier in this case (for employment changes) is 5.86.

Columns (5) and (6) turn to labor productivity. Here we find no robust patterns, which is not surprising since columns (1)–(4) document that the numerator and denominator move in the same direction and by similar amounts.

Table 2B reports multiple robustness checks. Our results are very similar without the own-shock term. Our baseline estimates are un-

weighted, and we obtain similar results when we weight observations by log 1991 value added or by 1991 employment levels. We also consider a series of more demanding specifications where we include a full set of two-, three-, and four-digit Standard Industrial Code (SIC) dummies. Since our specification in equation (12) is in changes, this amounts to including linear time trends for these industry groupings. The results are generally robust, although the downstream effects do move around and sometimes become larger, even if still far from significance.

The final column of table 2B returns to the resource-constraint effect identified in Proposition 1. As noted above, our baseline specifications focusing on demand-side shocks have ignored this resource-constraint effect, corresponding to the third term in equation (7). To the extent that this term is correlated with our network effect, it may lead to biased estimates. We compute the empirical equivalent of this third term following equation (7) closely. We sum nominal manufacturing imports from China to obtain the term $\sum_{k=1}^n d\tilde{G}_k$, multiply it with an estimate of β_j , computed as the value-added share of industry j , divide it by $p_j y_j$, and then multiply it with the corresponding entries of the Leontief inverse of the upstream linkages to obtain $\sum_{j=1}^n \hat{h}_{ji}(1 / p_j y_j) \beta_j \sum_{k=1}^n d\tilde{G}_k$ (ignoring the term $1 + \lambda$ in the denominator). We then add this term as an additional regressor instrumented by an additional instrument computed in the same way from Chinese imports by the same eight non-US-advanced economies. The final column of table 2B shows that this specification leads to somewhat larger network effects, but the overall picture remains unchanged.

Appendix table 2A repeats this analysis with log real-shipments growth as the outcome variable, and also shows similar results.²³

An additional issue is that the presence of the lagged dependent variable on the right-hand side of our estimating equation, (12), introduces the possibility of biased estimates when the time dimension is short due to the challenges of obtaining consistent estimates of the persistence parameter, ψ , with short panels as noted by Nickell (1981). We further investigate this issue in appendix table 2B. In particular, our main concern here is with the network effects, which may inherit the bias of the parameter ψ in short panels. One way of ensuring that this bias is not responsible for our results is to impose different values for the parameter ψ and verify that this has little or no impact on our results (see Acemoglu et al. 2014). Appendix table 2B performs this exercise for the China trade shock and documents that both own and upstream effects are highly significant and similar to our baseline estimates for any value

of ψ between our estimate of this parameter in table 2A ($\psi = 0$) and the full unit root limit ($\psi = 1$), becoming only a little weaker at the full unit root case of $\psi = 1$ (while downstream effects remain insignificant except marginally at $\psi = 1$).

Appendix table 2C considers longer time periods, thus linking our results more closely to Acemoglu et al. (2016), who focused on a decadal panel. For two-year periods, we prepare nine time periods from 1991–1993 to 2007–2009. For three-year periods, we consider six time periods from 1991–1994 to 2006–2009. For four-year periods, we consider four time periods from 1991–1995 to 2003–2007. For five-year periods, we consider 1991–1996, 1996–2001, and 2001–2006. In each case, the first period is used to create the network lags. The downstream customer effects and own-industry effects tend to grow with longer time periods.

In addition to these robustness checks, appendix table 6 shows very similar outcomes when we consider nominal value added and shipments growth instead of our baseline real value-added growth and the real shipments shown in appendix table 2A. Appendix table 7 also reports results where we vary the number of lags included for own-industry shocks and network shocks. We report in the table the sums of the coefficients across the deeper lags and their statistical significance. These variants yield quite similar conclusions to our reported estimations.

C. Federal Spending Shocks

The next analysis considers changes in US federal government spending levels, which are anticipated to operate similar to trade shocks by affecting industries through heightened demand from industrial customers. We first calculate from the 1992 BEA Input-Output Matrix the share of sales for each industry that went to the federal government,

$$FedSales\%_i = \frac{Sales_{i \rightarrow Fed}}{Sales_i}.$$

This share ranges from zero dependency for about 10% of industries to over 50% for the top percentile of industries in terms of dependency. Some prominent examples and their share of sales include 3731 Ship Building and Repairing (76%), 3761 Guided Missiles and Space Vehicles (74%), 3482 Small Arms Ammunition (65%), and 3812 Search, Detection, Navigation, Guidance, Aeronautical and Nautical Systems and Instruments (51%).

We interact this measure with the log change in federal government expenditures,

$$FederalShock_{i,t} = FedSales\%_i^{1991} \cdot \Delta \ln FederalSpending_{t-1},$$

holding fixed the industry dependency at its 1991 level. Intuitively, the specification anticipates greater shocks from aggregate federal budget changes for industries that have larger initial shares of sales to the federal government. The change in federal spending is lagged one year to reflect the fact that procurement frequently extends into the following year. Once again following (13) and (14), the downstream effects in this case are defined as

$$Downstream_{i,t}^{Federal} = \sum_j (Input\%_{j \rightarrow i}^{1991} - \mathbf{1}_{j=i}) \cdot FederalShock_{j,t}.$$

A similar approach is taken for the other network metrics.

Because this variable focuses on federal spending changes in the aggregate (driven by, among other things, swings in political moods, ideology, identity of the government, and wars and budget exigencies), and is then constructed with the interaction of these aggregate changes with the time-invariant and predetermined dependency of each industry on federal spending, we believe that it can be taken as plausibly exogenous to the contemporaneous productivity or supply-side shocks hitting the focal industry.

The structure of table 3A is identical to those examining trade shocks. The results are also similar. For example, in table 3A upstream effects are again significant and quantitatively sizable (about three to five times as large as own effects). Downstream effects are now of the same sign as the upstream effect, but continue to be statistically insignificant. The theory-implied restriction reported in the bottom row is again broadly supported (it is never rejected at 5%). In addition, the own effect is insignificant when we only control for one lag of the dependent variable, but significant both in columns (2) and (4) when we control for three lags.

Table 3B and appendix tables 3A–3C, 6, and 7 perform the same robustness checks as those discussed for trade shocks and show that the above-mentioned patterns are generally quite robust. All in all, the propagation of this very different demand-side shock appears remarkably similar to the propagation of the import shocks, and in both cases in line with the theory we have used to motivate our approach.

The economic magnitudes are once more far from trivial. Panel (B) of figures 1 and 3 depict the impulse response functions for own and upstream effects computed in the same way as for panel (A), and indicate

Table 3A

that there are once again sizable network effects. The implied network multipliers for value added and employment at the 10-year horizon are 6.42 and 5.00, respectively.

D. TFP Shocks

We next turn to supply-side shocks, starting with TFP. Baseline TFP shocks for manufacturing industries are the lagged change in four-factor TFP taken from the NBER Productivity Database. Importantly, these TFP measures control for materials, and thus should not be mechanically a function of downstream effects (changes in prices and quantities in industries supplying inputs to the focal industry).

Similar to our other network-based measures, these are constructed by aggregating these industry-level log components of TFP in connected industries. Continuing our illustration using downstream effects from shocks to supplier industries and again following on (13) and (14), we model

$$\text{Downstream}_{i,t}^{\text{TFP}} = \sum_j (\text{Input}_{j \rightarrow i}^{0,1991} - \mathbf{1}_{j=i}) \cdot \Delta \ln \text{TFP}_{j,t}.$$

We should caution that the case for the exogeneity of the TFP shocks is weaker, because past TFP may be endogenous to other shocks (e.g., to capacity utilization or labor hoarding), which have a persistent impact on value added and factor demands. With this caveat, we still believe that predetermined TFP shocks are informative about how supply-side shocks spread through the input-output network.

The structure of table 4A is identical to those examining trade and federal spending shocks. Consistent with theory, it is now downstream effects that are more sizable and important, though in this case there are some statistically significant estimates of upstream effects as well. For example, in column (1) of table 4A, downstream effects are estimated to have a coefficient of 0.060 (standard error = 0.020), while upstream effects come in at 0.024 (standard error = 0.011). Interestingly, own effects are small and imprecise for value added, but more precisely estimated (though still about half of the upstream effects) for employment. The theoretical restriction tested in the bottom row is now rejected for value added, where the own effects are small, but is in closer alignment for employment. The robustness checks reported in table 4B and in appendix B confirm this overall pattern.²⁴

Economic magnitudes can again be gleaned from panel (C) of figures 1 and 3; the implied multipliers are 15.56 and 4.43 for value-added growth

and employment growth over 10 years, respectively. The larger multiplier for value added in this case reflects the smaller direct (own) impact.

E. Foreign Patenting Shocks

Our final shock represents changes in patented technology frontiers. Since this shock also captures supply-side changes in productivity, responses to it should be similar to those to TFP shocks.

Baseline patent shocks for manufacturing industries in table 5A are the lagged log change in USPTO-granted patents filed by overseas inventors associated with the industry. We measure foreign patent shocks using United States Patent and Trademark Office (USPTO)-granted patents through 2009. We develop a new concordance of patent classes to four-digit manufacturing industries that extends the earlier work of Silverman (1999), Johnson (1999), and Kerr (2008). Continuing our downstream effects example, we have

$$\text{Downstream}_{i,t}^{\text{ForeignPatent}} = \sum_j (\text{Input}_{j \rightarrow i}^{1991} - \mathbf{1}_{j=i}) \cdot \Delta \ln \text{Patents}_{j,t}^{\text{Foreign}}.$$

These foreign patents quantify technology changes in the world technology frontier external to the US economy (e.g., patents filed by car manufacturers in Germany and Japan signal advances in automobile technologies that have not originated in the United States). There are two additional difficulties in this case, however. First, foreign patenting may be correlated with past technological improvements in the US sectors, which might have persistent effects. Second, improved technology abroad may directly impact US firms through fiercer product market competition, not just through technology and productivity spillovers (e.g., Bloom, Schankerman, and Van Reenen 2013).²⁵ These concerns make us more cautious in interpreting the foreign patenting shocks, especially for own effects, though we believe that this analysis is still informative about network-based propagation.

Table 5A shows strong downstream effects with again no evidence of sizable upstream effects. The theory-implied restrictions in the bottom row of the table are typically rejected, reflecting the very small and sometimes incorrectly signed estimates of own effects. One possible explanation for this pattern of own effects is that, as already noted, an increase in foreign patents in one's own industry likely signals fiercer competition from international competitors. The network effects, which should be less impacted by these considerations, are again quite similar to our theory's predictions. (Robustness checks on foreign patent shock analysis are shown in table 5B.)

Panel (D) of figures 1 and 3 again depict the impulse responses of value added and employment. We do not compute multipliers in this case, since the own effects are imprecisely estimated and potentially biased for the reasons explained above, thus making multiplier estimates harder to interpret.

F. VAR Analysis

Our empirical specification, (12), directly builds on our theoretical model (in particular, equations [6] and [7]), and expresses the endogenous response of value added and employment to shocks hitting all industries. An alternative is to follow vector auto regression (VAR) models and express endogenous variables as a function of own shocks and the values of the endogenous variables of linked industries. The analog of equation (12) in this case would be

$$\Delta \ln Y_{i,t} = \delta_t + \psi \Delta \ln Y_{i,t-1} + \beta^{\text{own}} \text{Shock}_{i,t-1} + \beta^{\text{upstream}} \Delta \ln Y_{i,t-1}^{\text{Upstream}} + \beta^{\text{downstream}} \Delta \ln Y_{i,t-1}^{\text{Downstream}} + \varepsilon_{i,t}, \quad (16)$$

which only features the shock hitting sector i , and models upstream and downstream effects from the changes in value added of linked industries—the terms $\Delta \ln Y_{i,t-1}^{\text{Upstream}}$ and $\Delta \ln Y_{i,t-1}^{\text{Downstream}}$. This equation could also be derived from our theoretical framework. Relative to our baseline empirical model, (12), this specification faces two related problems. First, the terms $\Delta \ln Y_{i,t-1}^{\text{Upstream}}$ and $\Delta \ln Y_{i,t-1}^{\text{Downstream}}$ generate a version of Manski's well-known reflection problem (Manski 1993), as outcome variables of one industry are being regressed on the contemporaneous (or one-period lagged) outcomes of other industries, creating the possibility of spurious correlation. Second, these terms are also more likely to be correlated with each other, potentially leading to multicollinearity, which will make distinguishing these various effects more difficult.

These problems notwithstanding, we now estimate equation (16) to show that the results from this complementary approach are broadly similar. To avoid the most severe form of the reflection problem, throughout we instrument for the upstream and downstream effects, $\Delta \ln Y_{i,t-1}^{\text{Upstream}}$ and $\Delta \ln Y_{i,t-1}^{\text{Downstream}}$, using the first and second lags of each shock as experienced in the network (i.e., our instruments are the core regressors in equation [12], $\text{Upstream}_{i,t-1}$ and $\text{Downstream}_{i,t-1}$). We report two specifications per shock. In the first, we model and instrument the focal part of the network relevant for each shock (e.g., upstream effects

for supply-side shocks and downstream effects for demand-side shocks). In the second specification, we include and instrument for both upstream and downstream effects. Also, in the case of China trade shocks, we continue to instrument for the own shock, $Shock_{i,t-1}$, as well.

The results of this exercise are reported in table 6 and are quite consistent with our baseline findings. Even though this empirical specification is more demanding for the reasons explained above, the specifications focusing on China trade and TFP shocks give similar results, and specifications using federal spending shocks also lead to similar results for value added, though not for employment. Foreign patenting results do not hold with this approach, however.²⁶

G. Combined Shock Analysis

Table 7 estimates own, upstream, and downstream effects simultaneously from several of the shocks so far analyzed in isolation. This is relevant for two related reasons. First, we would like to verify that our downstream and upstream effects indeed capture network-based propagation of different types of shocks rather than some other omitted characteristics, and attempting to simultaneously estimate these effects provides some information on this concern. Second, it is important to quantify whether the simultaneous operation of all of these networked effects creates attenuation, which is relevant for our quantitative evaluation.

Table 7 shows the estimates of upstream and downstream effects in this joint analysis are remarkably similar to our previous results. Appendix table 8 also shows this similarity when we exclude the foreign patenting shocks due to the concerns about own effects discussed above. These results bolster our confidence in the patterns documented so far and also suggest that the quantitative magnitudes of the propagation through these input-output networks is larger when we consider all four shocks simultaneously.

To quantify impacts from this joint exercise, we now consider one standard deviation changes of the three shocks, imports from China, federal spending and TFP, simultaneously. The impulse response functions from this exercise are shown in figure 2 in appendix B, and the combined multipliers for value added and employment growth in panels (A) and (B) are 11.47 and 8.23, respectively. Thus, the network elements jointly continue to account for more fluctuation than direct components. The lower panels show similar results when including foreign patenting shocks.

Notes: See tables 2A–5A. Rather than model network shocks directly, estimations consider intermediated approaches where the shock indicated by the column header instruments for changes in upstream and downstream economic activity in terms of real value added or employment. Estimations control for own shock and use two lags of upstream and downstream components. In each estimation pair, the first specification considers the focal network element for the shock in question. The second specification adds in the nonfocal element where the first stage fit can be weak.

H. Monte Carlo Verification

Though our empirical strategy so far has closely followed our theoretical model, there are several aspects in which the true data-generating process might be more complicated than the one implied by our model. First, our model abstracted from dynamic interactions between sec-

tors, whereas the original Long and Plosser (1983) paper assumed that an industry could only use as inputs at time t the output produced by other industries at time $t - 1$. This dynamic structure implies that rather than shocks being transmitted through the Leontief inverse of the input-output matrix as in our equations (6) and (7), they would be transmitted from one period to the next directly through the input-output matrix. Over time, this transmission would still lead to a cumulative impact as summarized by the Leontief inverse (as we show in appendix C).²⁷ Nevertheless, we might be concerned that this type of slow adjustment would lead to significant misspecification in our empirical work, where we impose equations (6) and (7). In appendix C, we conduct a Monte Carlo exercise where data are generated at quarterly frequency using the Long and Plosser (1983) timing (and shocks are serially correlated), and regressions are run at the annual frequency using the specifications we have utilized so far (thus filtering the observed shocks through the Leontief inverse of the input-output matrix). We find that the time averaging of the higher frequency data to annual observations ensures that specifications based on the Leontief inverse do not lead to any major misspecification. In particular, our results, described in detail in appendix figures 4–7, indicate that regressions run on time-averaged data can recover whether upstream or downstream linkages are important.

A second concern is whether measurement error in the input-output matrix might be significantly amplified when we compute the Leontief inverses. Another Monte Carlo exercise we perform in appendix C verifies that even if the input-output matrix is measured with error, regressions of the sort we have used are capable of recovering the correct parameters. We take these two Monte Carlo exercises as useful confirmation of the robustness and informativeness of our empirical strategy.

V. Additional Results: The Geographic Network

We next turn to an analysis of the geographic network's impact on the propagation of shocks. The theory in section II describes how shocks to an industry can also propagate regionally (e.g., within commuting zones) because they expand or depress economic activity, impacting the decisions of other industries in the area. Though a full analysis of these local interactions is beyond the scope of the present effort (see, for example, the treatment of Acemoglu et al. [2015] for medium-frequency import shocks on local economies), we can nonetheless get a sense of the importance of these channels of propagation by looking at the im-

impact of a shock to a particular industry on other industries that tend to collocate with it. This is essentially the idea of the geographic network introduced above.

Table 8 considers all four geographic effects simultaneously, which is particularly relevant since they are all working through the same local geographic networks. In columns (1) and (3) we only model own-industry effects and geographic spillovers, while columns (2) and (4) add the downstream and upstream network effects as well. Our most important observation from this analysis is the stability of the network effects compared to table 7. The latter continues to adhere to theory and shows that our network effects are not proxying for regional spillovers or similar local conditions. The second observation is that the geographic effects are almost always precisely estimated and are quite substantial in size for demand-side shocks.

Appendix table 9A shows that these joint patterns are robust to the specification checks considered earlier for input-output linkages. Appendix table 9B considers each of the four shocks in isolation rather than jointly modeling them. Similar to the results presented in table 8, the inclusion of geographic effects has little impact on our estimates of downstream and upstream network effects, which continue to adhere to theory. On the other hand, the geographic effects themselves are less stable and often substantially smaller when measured in isolation compared to the joint format. We thus remain cautious about strong interpretations of the size of the geographic effects compared to the overall stability that these specifications show for our network components.

With these caveats, the economic magnitudes of table 8's effects are substantial. Figure 3 in appendix B shows the impulse response functions including own and network effects in response to a one standard deviation shock in specifications that also include geographic effects, further reported in appendix table 9C. The implied magnitudes of some of these geographic effects are quite large and suggest a fruitful and important area for deeper investigation.²⁸

VI. Conclusion

Idiosyncratic firm- or industry-level shocks could spread through a network of interconnections in the economy, propagating and amplifying their initial impact. Though their potential import was initially downplayed because of the belief that their aggregation across many units (disaggregated industries or firms) would limit their macro-

*Significant at the 10 percent level.

economic impact, there has been a recent revival of interest in such network-based propagation of microeconomic shocks. This paper contributes to an empirical investigation of the role of such propagation, focusing primarily on input-output linkages but also on connections through the geographic collocation patterns of industries.

One feature that makes propagation through the input-output network particularly attractive for empirical study is that theory places fairly tight restrictions on the form of the transmission of these effects. In particular, in response to demand-side shocks, upstream propagation (to the suppliers of the directly affected industries) should be more pronounced than downstream propagation (to the customers of the directly affected industries), whereas in response to supply-side shocks, the reverse ordering should hold. In fact, when production technologies and consumer preferences are Cobb-Douglas, there should only be upstream propagation with demand-side shocks and only downstream propagation with supply-side shocks. Moreover, the quantitative magnitudes of the direct effects and the downstream/upstream effects are pinned down by theory.

After reviewing these theoretical basics, we turn to an empirical investigation of the propagation of four different types of shocks—China import shocks and federal government spending shocks on the demand side, and TFP and foreign patenting shocks on the supply side. In each case, we study these shocks first in isolation and then in combination with the other shocks, and separately estimate own (direct) effects as well as downstream and upstream effects. Throughout, our focus is on annual variation, which appears more relevant for the question of macroeconomic fluctuations, though we verify the robustness of our results to lower-frequency analysis.

Our empirical results paint a fairly uniform pattern across the different types of shocks. In each case, the patterns are consistent with theory—in the case of demand-side shocks, upstream effects strongly overshadow downstream effects, which are often zero or in the opposite direction, and the converse is true with supply-side shocks. Moreover, the theory-implied quantitative restrictions are often verified, excepting the foreign patenting shocks. Equally important, we also find the network-based propagation of shocks to be quantitatively sizable, and in each case, more important than the direct effect of the shock—sometimes more than five times as important. These patterns appear to be fairly robust across specifications and different control strategies.

In addition to the propagation of shocks through the input-output network, the geographic spread of economic shocks could potentially

be important. For example, many economic transactions, particularly for nontradables, take place within the local economy (e.g., a county or commuting zone). If so, a negative shock to an industry concentrated in an area will impact firms and workers in that area. Though a full analysis of this geographic dimension requires detailed data with geography/industry breakdown, we also undertake a preliminary investigation of these linkages by focusing on the collocation patterns of industries. The idea is simple: if two industries tend to collocate strongly, meaning that wherever one industry plays a major role in the local economy, the other industry is also likely to be overrepresented, then shocks to the first industry will tend to be felt more strongly by this collocating industry than other, geographically less connected industries. We derive a theoretical relationship showing how industry-level shocks spread to other industries depending on collocation patterns and then empirically investigate this linkage.

Our results in this domain are somewhat less robust, but still indicate a fairly sizable impact of the propagation of shocks through the geographic collocation network. In fact, quantitatively this channel appears to be, if anything, somewhat more important than the transmission of shocks to the input-output network. Interestingly, however, controlling for this geographic channel does not attenuate or weaken the evidence we find for the propagation of shocks with the input-output network.

Though ours is not the first paper showing that certain shocks spread through the network of input-output linkages (and also of geographic connections), we still consider our paper as part of the early phase of this emerging literature documenting the empirical power of network-based propagation of shocks. Several areas of future work look promising from our vantage point. First, as already noted, the geographic spread of shocks can be better studied by using data and empirical methods that cover multiple geographic scales and levels of interaction, and even better would be to incorporate measures of the geographic span of the operations and plants of multiunit firms using the Census Bureau's Longitudinal Business Database.

Second, the input-output network we utilize is still fairly aggregated. The theoretical logic applies at any level of disaggregation, and even at the level of firms. Though firm input-output linkages require some care (since many such relations may be noncompetitive due to the presence of relationship-specific investments or holdup problems), the same ideas can also be extended to the firm-level network of input-output linkages. Atalay, Hortacsu and Syverson (2014) and Atalay et al. (2011)

take first steps in constructing such firm-level networks, which can then be used for studying this type of propagation.

Third, the simple but powerful nature of the theory we have already exploited in this paper also suggests that more structural approaches could be quite fruitfully applied in this domain, which will enable more rigorous testing of some of the theoretical predictions of this class of models. For example, the Leontief inverse matrix also puts a considerable amount of discipline about the comovement of value added and employment across industries resulting from shocks spreading through the input-output network, which can be formally investigated.

Fourth, the role of the input-output and the geographic networks in the propagation of industry-level (micro)shocks suggests that these networks may also be playing a role in the amplification of macroshocks—such as aggregate demand, monetary and financial shocks—which appears to be a generally understudied area.

Fifth, the two types of networks we have focused on are by no means the only ones that may matter for macroeconomic outcomes. Two others that have recently been investigated are the financial network, which can lead to the propagation and contagion of shocks hitting some financial institutions to the rest of the financial system (e.g., Allen and Gale 2000; Acemoglu et al. 2015c; Elliott, Golub, and Jackson 2014; Cabrales, Gottardi, and Vega-Redondo 2014), and the idea/innovation network, which can lead to the spread of new knowledge, innovations, and practices (studied, for example, in Acemoglu, Akcigit, and Kerr [2015], as well as indirectly in Bloom et al. [2013]). Our decision to abstract from these was partly because of our empirical frame, which centers on industry-level shocks, and also because of our focus on shorter-run fluctuations (whereas the propagation of new ideas and innovations through the innovation network is likely to be more important at five- or ten-year frequencies or even longer). Nevertheless, combining these various types of network linkages may be a fruitful area for future research.

Finally, in addition to the propagation of shocks to other industries or firms, the network linkages emphasized here can also fundamentally change the nature of macroeconomic outcomes and their volatility. For example, Acemoglu et al. (2015a) show how tail macroeconomic risk can be created from the propagation of microeconomic shocks through the input-output network, while Schennach (2013) suggests that these types of network effects may change the persistence properties of macro-

economic time series. These new areas also constitute fruitful directions for future research.

Appendix A

Proof of Proposition 1

Part 1. Let us set government purchases equal to zero for this part of the proof. Recall that profit maximization implies

$$a_{ij} = \frac{p_j x_{ij}}{p_i y_i}, \text{ and } \alpha_i^l = \frac{w l_i}{p_i y_i}. \tag{A1}$$

Utility maximization in turn yields

$$\frac{p_i c_i}{\beta_i} = \frac{p_j c_j}{\beta_j}. \tag{A2}$$

Since total household income is equal to labor income, and in this part we have no government purchases, we also have

$$\sum_{i=1}^n p_i c_i = w l,$$

which yields

$$p_i c_i = \beta_i w l, \forall i. \tag{A3}$$

Moreover, the first-order condition for labor supply implies

$$-\frac{\gamma'(l)}{\gamma(l)} = 1,$$

and thus labor supply is determined independent of the equilibrium wage rate because given the preferences in (3), income and substitutions cancel out.

Let us now take logs in (1) and totally differentiate to obtain

$$d \ln y_i = dz_i + \alpha_i^l d \ln l_i + \sum_{j=1}^n a_{ij} d \ln x_{ij}. \tag{A4}$$

Let us next totally differentiate (A1) to obtain

$$d \ln y_i + d \ln p_i = d \ln x_{ij} + d \ln p_j,$$

and

$$d \ln y_i + d \ln p_i = d \ln l_i,$$

where we have made use of the fact that the wages are chosen as the numeraire and thus $d \ln w = 0$. Substituting these two equations into (A4), we have

$$d \ln y_i = dz_i + \alpha_i^l (d \ln y_i + d \ln p_i) + \sum_{j=1}^n a_{ij} (d \ln y_i + d \ln p_i - d \ln p_j).$$

Next recalling that l remains constant, differentiating (A2) and (A3), and combining with the previous two equations to eliminate prices, we obtain

$$d \ln y_i = dz_i + \alpha_i^l (d \ln y_i - d \ln c_i) + \sum_{j=1}^n a_{ij} (d \ln y_i - d \ln c_i + d \ln c_j).$$

Noting that $\alpha_i^l + \sum_{j=1}^n a_{ij} = 1$, this simplifies to

$$d \ln c_i = dz_i + \sum_{j=1}^n a_{ij} d \ln c_j,$$

which can be rewritten in matrix form as

$$\mathbf{d} \ln \mathbf{c} = \mathbf{d} \mathbf{z} + \mathbf{A} \mathbf{d} \ln \mathbf{c}$$

where $\mathbf{d} \ln \mathbf{c}$ and $\mathbf{d} \mathbf{z}$ are the vectors of $d \ln c_i$ and dz_i respectively, which is a unique solution given by

$$\mathbf{d} \ln \mathbf{c} = (\mathbf{I} - \mathbf{A})^{-1} \mathbf{d} \mathbf{z}, \quad (\text{A5})$$

in view of the fact that the largest eigenvalue of \mathbf{A} is less than 1. Next combining (2) and (A1), we have

$$\frac{y_j}{c_j} = 1 + \sum_{i=1}^n a_{ij} \frac{\beta_i y_i}{\beta_j c_i},$$

which implies that

$$\mathbf{d} \ln \mathbf{y} = \mathbf{d} \ln \mathbf{c}. \quad (\text{A6})$$

Then combining (A5) with (A6) we obtain

$$\mathbf{d} \ln \mathbf{y} = (\mathbf{I} - \mathbf{A})^{-1} \mathbf{d} \mathbf{z}. \quad (\text{A7})$$

This yields the desired result, (6).

Part 2. Normalize $\mathbf{z} = \mathbf{0}$ for this part of the proof. Consider the unit cost function of sector i , which is

$$C_i(\mathbf{p}, w) = B_i w^{\alpha_i^l} \prod_{j=1}^n p_j^{a_{ij}},$$

where

$$B_i = \left[\frac{1}{\alpha_i^l} \right]^{\alpha_i^l} \prod_{j=1}^n \left[\frac{1}{a_{ij}} \right]^{a_{ij}}.$$

Zero profit condition for producer i implies

$$\ln p_i = \ln B_i + \alpha_i^l \ln w + \sum_{j=1}^n a_{ij} \ln p_j \text{ for all } i \in \{1, \dots, n\}.$$

Since the wage is the numeraire (i.e., $w = 1$), we have $\alpha_i^l \ln w = 0$ and these equations define an n equation system in n prices (for a given vector of productivities \mathbf{z} , in this instance normalized to 1), with solution

$$\ln \mathbf{p} = (\mathbf{I} - \mathbf{A})^{-1} \mathbf{b},$$

where \mathbf{b} is the vector with entries given by $\ln B_i$.

This shows that, for a given vector of productivities, the equilibrium price vector is uniquely determined regardless of the value of the vector of government purchases \mathbf{G} . Thus demand-side shocks have no impact on equilibrium prices, which are entirely determined by the supply side. But then from (A3), the consumption vector remains unchanged, and from (2), total net supply of all sectors has to remain constant regardless of the change in \mathbf{G} . We can then obtain the change in the total production in the economy using (2) combined with (A1) and (A2), which with unchanged prices simply implies

$$d \ln y_i = d \ln x_{ij} \text{ and } d \ln y_i = d \ln l_i.$$

Household maximization implies that, even though prices are fixed, labor supply will change because of changes in consumption (resulting from government purchases). In particular, the following first-order condition determines the representative household's labor supply

$$\frac{wl}{wl - T} = - \frac{l\gamma'(l)}{\gamma(l)},$$

with $T = \sum_{i=1}^n p_i G_i$.

When $\gamma(l) = (1 - l)^\lambda$, using the fact that the wage, w , is chosen as the numeraire, we obtain

$$l = \frac{1 + \lambda \sum_{i=1}^n p_i G_i}{1 + \lambda}.$$

Therefore, we have that

$$p_i c_i = \beta_i [lw - T]$$

$$= \frac{\beta_i}{1 + \lambda} \left[1 - \sum_{j=1}^n p_j G_j \right]$$

which implies

$$d(p_i c_i) = - \frac{\beta_i}{(1 + \lambda)} \sum_{j=1}^n d(p_j G_j).$$

The resource constraint then implies:

$$dy_i = dc_i + \sum_{j=1}^n dx_{ji} + dG_i.$$

Combining the previous two equations with (A1),

$$\frac{d(p_i y_i)}{p_i y_i} = \sum_{j=1}^n a_{ji} \frac{d(p_j y_j)}{p_j y_j} + \frac{dG_i}{y_i} - \frac{\beta_i}{(1 + \lambda)} \sum_{j=1}^n \frac{d(p_j G_j)}{p_j y_j} \tag{A8}$$

$$= \sum_{j=1}^n \hat{a}_{ji} \frac{d(p_j y_j)}{p_j y_j} + \frac{d\tilde{G}_i}{p_i y_i} - \frac{\beta_i}{(1 + \lambda)} \sum_{j=1}^n \frac{d\tilde{G}_j}{p_i y_i},$$

where $\tilde{G}_j = p_j G_j$. Writing this in matrix form and noting that, because prices are constant, $d(p_i y_i) / p_i y_i = d \ln y_i$, we have

$$d \ln \mathbf{y} = \hat{\mathbf{A}}^T d \ln \mathbf{y} + \Lambda d \tilde{\mathbf{G}}$$

$$= (\mathbf{I} - \hat{\mathbf{A}}^T)^{-1} \Lambda d \tilde{\mathbf{G}}$$

$$= \hat{\mathbf{H}}^T \Lambda d \tilde{\mathbf{G}}$$

where $\hat{\mathbf{H}} = (\mathbf{I} - \hat{\mathbf{A}})^{-1}$, $\tilde{\mathbf{G}}$ is the vector of nominal government spending levels, the \tilde{G} 's,

$$\hat{\mathbf{A}} = \begin{pmatrix} \hat{a}_{11} & \hat{a}_{12} & \dots & & \\ \hat{a}_{21} & \hat{a}_{22} & & \ddots & \\ & & \ddots & & \\ & & & & \hat{a}_{mm} \end{pmatrix},$$

with entries $\hat{a}_{ij} = x_{ij} / y_i$, and

$$\Lambda = \begin{pmatrix} \left(1 - \frac{\beta_1}{(1 + \lambda)}\right) \frac{1}{p_1 y_1} & -\frac{\beta_1}{(1 + \lambda)} \frac{1}{p_1 y_1} & \dots & & \\ -\frac{\beta_2}{(1 + \lambda)} \frac{1}{p_2 y_2} & \left(1 - \frac{\beta_2}{(1 + \lambda)}\right) \frac{1}{p_2 y_2} & & & \\ & & \ddots & & \\ & & & & \left(1 - \frac{\beta_n}{(1 + \lambda)}\right) \frac{1}{p_n y_n} \end{pmatrix}. \tag{9}$$

Carrying out the second matrix multiplication, this can also be written as

$$d \ln \mathbf{y} = \hat{\mathbf{H}}^T \begin{pmatrix} \frac{d\tilde{G}_1}{p_1 y_1} - \frac{\beta_1}{(1 + \lambda)} \frac{1}{p_1 y_1} \sum_{j=1}^n d\tilde{G}_j \\ \frac{d\tilde{G}_2}{p_2 y_2} - \frac{\beta_2}{(1 + \lambda)} \frac{1}{p_2 y_2} \sum_{j=1}^n d\tilde{G}_j \\ \vdots \end{pmatrix},$$

or with one more round of matrix multiplication, as

$$d \ln y_i = \sum_{j=1}^n \hat{h}_{ji} \frac{1}{p_j y_j} \left(d\tilde{G}_j - \frac{\beta_j}{1 + \lambda} \sum_{k=1}^n d\tilde{G}_k \right).$$

Rearranging this equation yields (7).

We also note that the effects of demand-side shocks can be alternatively expressed (without the division by $p_i y_i$ in equation [A8]) in level, rather than log, changes as

$$d\tilde{\mathbf{y}} = \mathbf{H}^T \begin{pmatrix} d\tilde{G}_1 - \frac{\beta_1}{(1 + \lambda)} \sum_{j=1}^n d\tilde{G}_j \\ d\tilde{G}_2 - \frac{\beta_2}{(1 + \lambda)} \sum_{j=1}^n d\tilde{G}_j \\ \vdots \end{pmatrix}, \tag{10}$$

which is the general form of the expressions used in Example 2.

Endnotes

Authors' addresses (respectively): Massachusetts Institute of Technology, University of Pennsylvania, and Harvard University. This is a revised paper that was presented at the 30th Annual Conference on Macroeconomics. We are grateful to the organizers/editors, Martin Eichenbaum and Jonathan Parker, and our discussants, Lawrence Christiano and Xavier Gabaix, for their very helpful directions and comments. We also thank seminar participants for their comments and ideas, Brendan Price and Pascual Restrepo for data assistance, and Alexis Brownell for excellent research assistance. The online appendices for this paper are available with our NBER working paper and also at www.people.hbs.edu/wkerr. For acknowledgments, sources of research support, and disclosure of the authors' material financial relationships, if any, please see <http://www.nber.org/chapters/c13598.ack>.

1. Earlier contributions on this theme include Jovanovic (1987) and Durlauf (1993) who showed how idiosyncratic shocks can accumulate into aggregate risk in the presence of strong strategic complementarities, and Bak et al. (1993) who proposed a model of macroeconomic "self-organized criticality" capable of generating macroeconomic fluctuations from small shocks due to nonlinear interactions between firms and industries.

2. Acemoglu, Akcigit, and Kerr (2015) look at the medium-run spread of new ideas through the innovation (knowledge-flow) network of the US economy.

3. Though our evidence shows that microeconomic (industry-level) shocks are important and propagate strongly, it does not directly speak to the issues discussed in the previous paragraph, that is, to whether a law of large numbers-type argument will ensure that they wash out at the macrolevel.

4. We should add at this point that despite our use of the term "shocks," we would like to be cautious in claiming that our estimates correspond to causal effects of purely exogenous shocks on endogenous economic outcomes. Even though we specify our regression equations to guard against the most obvious forms of endogeneity (contemporaneous shocks affecting both left- and right-hand-side variables and Manski's [1993] reflection problem that would result from having grouped endogenous variables on the right-hand side), our shocks themselves may be endogenous to economic decisions in the recent past. For imports from China, because we are focusing on the exogenous component of the variation, we are fairly confident that our estimates are informative about causal effects. The same applies, perhaps with some additional caveats, to federal-spending shocks, since we exploit variation across industries in their differential responsiveness to such aggregate changes. For the TFP and foreign-patenting measures, the endogeneity concerns are more severe. Nevertheless, even in these cases we believe that our regressions are informative about the propagation of these "predetermined" shocks through the input-output and geographic networks.

5. Here, consistent with theory, "network effects" refer to downstream effects for supply-side shocks and upstream effects for demand-side shocks. The details of how figure 1 is constructed are provided below.

6. Recent work looking at the local coagglomeration of industries includes Ellison, Glaeser, and Kerr (2010), Greenstone, Hornbeck, and Moretti (2010), and Helsley and Strange (2014).

7. Appendices B and C are available online (<http://www.nber.org/data-appendix/c13598/online-appendix.pdf>).

8. The main results we emphasize do not depend on the absence of physical capital, for example, with a production function that takes the form

$$y_i = e^{z_i} h_i^{\alpha_i} k_i^{\alpha_i^k} \prod_{j=1}^n x_{ij}^{\alpha_{ij}^j}.$$

We suppress capital to simplify the notation and discussion.

More consequential is our assumption that this is a static economy where each industry simultaneously buys inputs from others. Long and Plosser (1983) instead assumed that

an industry at time t uses as inputs products produced by other industries at date $t - 1$. We discuss the implications of our timing assumption and the robustness of our results to this structure in appendix C (<http://www.nber.org/data-appendix/c13598/online-appendix.pdf>, available online).

9. The diagonals of the Leontief inverse matrix, \mathbf{H} , are no less than 1, so that $h_{ii} - 1$ is nonnegative.

10. In this case, the functional form assumption $\gamma(l) = (1 - l)^\alpha$ is imposed to simplify the expressions.

11. Detailed derivations for this and the next example are provided in appendix C, available online.

12. Clearly Cobb-Douglas is an approximation, though arguably not a bad one since the US input-output matrix appears to be fairly stable over time, as shown, for example, in Acemoglu et al. (2012) (and with non-Cobb-Douglas technologies this would not be the case). Our empirical results also give additional credence to the notion that Cobb-Douglas is a useful approximation for our purposes. In any case, it should be emphasized that the qualitative nature of the results emphasized in the proposition—that supply shocks will have larger downstream effects than upstream effects—holds true with non-Cobb-Douglas technologies and preferences, since even in this case quantity and price effects would at least partially offset each other (and in fact, Acemoglu, Ozdaglar, and Tahbaz-Salehi [2015b] show that similar results to those in Proposition 1 can be obtained as first-order approximations under general production technologies).

13. In fact, this equation implies that the coefficients of the own and network effects should both be equal to one, though this prediction depends on the choice of units of the shocks, the dz 's. In practice, the coefficients will be different than one but still equal to each other depending on the specific choices of units for measuring our shocks.

14. This can be seen straightforwardly by considering a dynamic version of the model (without additional intertemporal linkages), in which case equations (6) and (7) would apply with time subscripts, with only dz_{it} being relevant for time t outcomes. In the presence of irreversible investments and/or other intertemporal linkages at the sectoral level, expectations of future shocks would also matter.

15. More formally, when η is small, the inverse $(\mathbf{I} - \mathbf{B})^{-1}$ necessarily exists, and thus has an infinite series expansion of the form:

$$(\mathbf{I} - \mathbf{B})^{-1} = \mathbf{I} + \mathbf{B} + \mathbf{B}^2 + \mathbf{B}^3 + \dots$$

Moreover, when η is small, we can also approximate this inverse with the first two terms, which leads to the next equation. We describe below calculations and empirical tests with higher-order terms.

16. Available online (<http://www.nber.org/data-appendix/c13598/online-appendix.pdf>).

17. We use this notation rather than h_{ij} as in section II to emphasize that these are the empirical counterparts of the theoretical notions developed above.

18. First-stage equations also naturally control for all other covariates from the second stage, including the lagged dependent variable, to ensure consistent estimation. But, of course, the only excluded instrument is the exogenous component of the change in import penetration.

19. [Http://www.nber.org/data-appendix/c13598/online-appendix.pdf](http://www.nber.org/data-appendix/c13598/online-appendix.pdf).

20. The unweighted standard deviation in industry growth rates for our sample is 0.15 for log value-added growth and 0.10 for log employment growth.

21. This restriction is not tested directly from the reported regression, but from the related regression described in section II, following Proposition 1, where own effects reflect the diagonal elements of the Leontief inverse matrix. We report specifications in which the own effects are not scaled in this manner to maintain transparency about the direct first-order effects of own-industry shocks. In any case, the coefficient estimates when we undertake this scaling are similar to those reported in the tables in the paper.

22. More specifically, focusing on upstream effects, recall that $Upstream_{i,t} = \sum_j (Output_{j,t}^{1991} - \mathbf{1}_{j=i}) \cdot Shock_{j,t}$, whereas for this term to capture the quantitative impact of shocks on supplier industries, we would need it to take the form

$$\sum_j \frac{(\text{Output}\%_{i \rightarrow j}^{1991} - \mathbf{1}_{j=i})}{\sum_k (\text{Output}\%_{i \rightarrow k}^{1991} - \mathbf{1}_{k=i})} \cdot \text{Shock}_{i,t}$$

so that it corresponds to a weighted average of shocks hitting industries.

The simplest and most transparent approach to make this adjustment is to divide our coefficient estimates by the average of the $\sum_k (\text{Output}\%_{i \rightarrow k}^{1991} - \mathbf{1}_{k=i})$'s, i.e., by $(1/n) \sum_k (\text{Output}\%_{i \rightarrow k}^{1991} - \mathbf{1}_{k=i})$ (where n is the number of industries). The adjustment for the downstream effect is very similar. From the US input-output matrix, this adjustment factor is 2.156.

An alternative method would be to rerun all of our specifications using the adjusted upstream and downstream measures (computed as weighted averages as indicated above). This method yields estimates of network multipliers for value added and employment of 5.9 and 8.0, respectively, which are comparable to the 6.4 and 5.9 multipliers estimated by the direct-adjustment method outlined here and reported below.

23. All appendix tables are included in appendix B (<http://www.nber.org/data-appendix/c13598/online-appendix.pdf>).

24. However, in this case, appendix table 4B shows that the results are sensitive to the exact value of the persistence parameter, ψ .

25. Bloom et al. (2013) develop a strategy for controlling for this competition effect, but the implementation of their strategy is not feasible given our industry-level data.

26. Appendix figure 1 reports impulse response functions akin to figures 1a and 1b using the results from table 6, where we trace out a one standard deviation upstream or downstream network component in terms of value added or employment, as instrumented by each shock, alongside the direct effect of the shock. For brevity, we only plot the stable and theory-consistent estimates, which are the ones that are meaningful to compare to our baseline results. The resulting magnitudes are comparable to, though somewhat larger than, our main estimates.

27. Available at <http://www.nber.org/data-appendix/c13598/online-appendix.pdf>.

28. Following Autor et al. (2013), Acemoglu et al. (2015) estimate an aggregate reduction of over 1.5 million manufacturing jobs through direct and network effects from the China trade shocks. In terms of our framework, their estimates correspond to a combination of own effects and geographic spillovers; they also control for changes in the underlying population in regions in their econometric specification.
